COMPUTATION OF HELICOPTER ROTOR WAKE GEOMETRY AND  
ITS INFLUENCE ON ROTOR HARMONIC AIRLOADS

by

Michael P. Scully

Submitted to the Department of Aeronautics and Astronautics  
on January 27, 1975 in partial fulfillment of the requirements  
for the degree of Doctor of Philosophy.

ABSTRACT

Efficient techniques are developed for the computation of helicopter rotor tip vortex geometry and helicopter rotor harmonic airloads. These techniques are designed to minimize the computational expense by the use of simplified wake models together with other devices which reduce the amount of integration over the wake of the Biot Savart relation for induced velocity. These techniques are designed for use in steady-state flight at advance ratios below 0.3; however, they could be readily extended to higher advance ratios and to transient flight conditions.

The results of the tip vortex geometry computations show that, over the forward portion of the rotor, the tip vortex is actually much closer to the rotor than the classical rigid wake assumption would indicate. This results in very intense, close blade-tip vortex interactions. These interactions must be modeled much more carefully than the less intense ones which occur when the rigid wake geometry assumption is used. The use of a lifting-surface solution for the airloads induced by these close blade-tip vortex interactions resulted in a substantial improvement in the agreement with measured airloads. Further improvement was obtained by the use of a very simplified model for tip vortex-core bursting and for the propagation of that bursting ahead of the blade which initiated it. This, together with the lifting-surface solution, brought the computed airloads into reasonable agreement with the measured airloads.

A simple tip vortex roll-up model was used to test the effect of roll-up on the airloads computation and it was found to be significant in some cases. The effects of tangentially-induced velocity and local separation on airloads computations were also evaluated and found to be of limited importance. It is recommended that close blade-vortex interactions and tip vortex formation and roll-up be studied both experimentally and theoretically. The currently

available knowledge of these phenomena is inadequate for accurate harmonic airloads computations.

## ACKNOWLEDGMENTS

Grateful acknowledgment is made to Professor R.H. Miller and to Professor N.D. Ham for their advice and inspiration and especially for their friendship. Professor Miller introduced me to this line of research and his continuing advice and supervision has been invaluable. Professor Ham taught me the fundamentals of rotary winged aircraft and has read the manuscript with painstaking care, suggesting many valuable improvements. Professor Ham's family has become my family here on the East coast and there are many happy memories of holidays spent together.

I would also like to thank Professor E.E. Covert and Professor W.S. Lewellen for helpful discussions and advice. Mrs. Gertrude Hubbard deserves especial thanks for her very rapid and efficient typing of this manuscript from a handwritten draft.

This work has been supported by the U.S. Naval Air Systems Command, Airframe Division, largely under contracts N00019-73-C-0378 and N00019-74-C-0321.

# LIST OF SYMBOLS\*

$a$	$\frac{\partial C_L}{\partial \alpha}$ before corrections for Mach number and dynamic stall
$\vec{a}, \vec{b}$	Vectors from point $P_\eta$ to points $P_a$ and $P_b$ on vortex segment (normalized by $R$ ) (Fig. 16)
$a_0, a_1, a_2, b_1, b_2$	Harmonics of rigid blade flapping. $\beta(\psi) = a_0 - a_1 \cos\psi - b_1 \sin\psi - a_2 \cos 2\psi - b_2 \sin 2\psi \dots$
$a_R$ - LDS	Artificial $\partial C_L / \partial \alpha$ including radial flow and dynamic stall effects
$(axb)_i, (axb)_j, (axb)_k$	$x, y, z(\vec{i}, \vec{j}, \vec{k})$ components of $\vec{axb} = (axb)_i \vec{i} + (axb)_j \vec{j} + (axb)_k \vec{k}$
$b$	Rotor blade semi-chord (ft)
$c$	Rotor blade average chord (ft)
$\vec{c}$	Vector along vortex line segment from point $P_a$ to point $P_b$ (normalized by $R$ ). $\vec{c} = \vec{b} - \vec{a}$ (Figs. A1, B2)
$c_a, c_b$	Distances along vortex-line segment ( $\vec{c}$ ) from perpendicular dropped from point $P_\eta$ to $\vec{c}$ to point $P_a$ and $P_b$ (normalized by $R$ ) (Fig. B2)
$C_T$	Thrust coefficient. $C_T = \frac{\text{thrust (lb)}}{\rho \pi R^2 (\Omega R)^2}$
$\vec{D}(\phi, \delta)$ - LDS	Tip vortex distortion at point $P_\ell$ (normalized by $R$ ) (Subsection 1.5)
$\vec{D}(\phi, \delta_\ell)$ - WG	Tip vortex distortion of point $P_\ell$ (normalized by $R$ )
$\vec{D}(\psi, \delta)$ - WG	Tip vortex distortion at point $P_\eta$ (normalized by $R$ )

\* The notation (LDS) means that the symbol is used in only the airloads computation or that it has a special definition when used in the airloads computation. The notation (WG) means that the symbol is used in only the wake geometry computation or that it has a special meaning when used in the wake geometry computation. No notation means that the symbol is used in both computations.

$D_1(\phi, \delta),$	} LDS	$x, y, z$ components of $\vec{D}(\phi, \delta)$
$D_2(\phi, \delta),$		$\vec{D}(\phi, \delta) = D_1(\phi, \delta)\vec{i} + D_2(\phi, \delta)\vec{j} + D_3(\phi, \delta)\vec{k}$
$D_3(\phi, \delta)$		(normalized by R)
$\vec{D}_\ell(\phi, \delta_\ell) -$ WG		Best estimate of distortion at point $P_\ell$ (normalized by R) (Subsection 4.1.6)
$D_{\ell x}(\phi, \delta_\ell),$	} WG	$x, y, z$ components of $\vec{D}_\ell(\phi, \delta_\ell)$
$D_{\ell y}(\phi, \delta_\ell),$		$\vec{D}_\ell(\phi, \delta_\ell) = D_{\ell x}(\phi, \delta_\ell)\vec{i} + D_{\ell y}(\phi, \delta_\ell)\vec{j}$
$D_{\ell z}(\phi, \delta_\ell)$		$+ D_{\ell z}(\phi, \delta_\ell)\vec{k}$ (normalized by R)
$\vec{D}_O(\psi) -$ WG		Old value of $\vec{D}(\psi, \delta)$ which was replaced by the most recent updated value of $\vec{D}(\psi, \delta)$ in the $\vec{D}$ table (normalized by R)
$\vec{D}_S(\psi) -$ WG		Assumed value of $\vec{D}(\psi, \delta_M - \Delta\psi)$ which has been replaced by a new computed value in the $\vec{D}$ table (normalized by R)
$\vec{D}_\eta(\psi, \delta) -$ WG		Best estimate of distortion at point $P_\eta$ (normalized by R) (Subsection 4.1.6)
$D_{\eta x}(\psi, \delta),$	} WG	$x, y, z$ components of $\vec{D}_\eta(\psi, \delta)$
$D_{\eta y}(\psi, \delta),$		$\vec{D}_\eta(\psi, \delta) = D_{\eta x}(\psi, \delta)\vec{i} + D_{\eta y}(\psi, \delta)\vec{j}$
$D_{\eta z}(\psi, \delta)$		$+ D_{\eta z}(\psi, \delta)\vec{k}$ (normalized by R)
$EI(\bar{\eta}) -$ LDS		Rotor blade radial distribution of flapwise stiffness (lb-ft <sup>2</sup> )
$f_t(\phi, \delta) -$ LDS		Fraction of total tip vortex circulation concentrated in tip vortex line at azimuth angle $\phi$ and age $\delta$ . $f_t(\phi, \delta) = f_t^O(\phi) + \delta * f_t^D$
$f_t^D -$ LDS		Tip vortex roll-up rate - $f_t(\phi, \delta)$ increases by $\Delta\phi * f_t^D$ for every $\Delta\phi$ increase in age $\delta$
$f_t^O(\phi) -$ LDS		Fraction of total tip vortex circulation concentrated in tip vortex line at azimuth angle $\phi$ and zero age
$F -$ LDS		Theodorsen lift deficiency function

$F_c$ - LDS	Correction factor for tip vortex line segment contribution to induced velocity, accounts for all vortex core and close blade-vortex interaction effects
	$F_c = q_f * \gamma_c(\rho)$
$G_M(\eta, \psi)$ - LDS	Glauert Mach number correction, $\frac{\partial C_L}{\partial \alpha} = \frac{a}{G_M(\eta, \psi)}$
	$G_M(\eta, \psi) = \text{Max} \begin{cases} \sqrt{1 - (\eta + \mu \sin \psi)^2 M_T^2} \\ 0.60 \end{cases}$
$h, h_1, \vec{h}$	Perpendicular distance for point $P_\eta$ to a vortex line segment or the forward edge of a vortex sheet segment (normalized by R). (Figs. A1, B2)
$i$	Angle of incidence of relative wind to TPP (Fig. 15)
$\vec{i}, \vec{j}, \vec{k}$	Unit vectors along x, y, z axes (Fig. 16)
$\vec{i}_x, \vec{i}_y, \vec{i}_z$	Unit vectors along $\vec{x}, \vec{y}, \vec{z}$ axes (Fig. B1)
$I_0, I_1, I_2, I_3$ (Subsection 3.3.1) - LDS	Integrals in harmonic blade motion solution (see Eqs. 3.118 to 3.121)
$I_1, I_2, I_3, I_4$ (Appendix B)	Vortex sheet segment integrals (see Eqs. B.10 to B.13)
$I_b$ - LDS	Rotor blade flapwise moment of inertia about the flapping hinge (slug-ft <sup>2</sup> )
$\ell, \ell_\ell$	Radial station on $\ell$ blade of point $P_\ell$ from which an element of vortex wake is shed (normalized by R) (Figs. 5, 16)
$\ell_i(\phi)$ - LDS	Radial station on $\ell$ blade of outboard edge of inboard trailing vortex sheet (normalized by R) (Subsection 2.5.3)
$\ell_t(\phi)$ - LDS	Radial station on $\ell$ blade of inboard edge of tip vortex sheet (normalized by R) (Subsection 2.5.3)

$\Delta l_{xy}$ - LDS	Distance in TPP from point $P_a$ on the vortex line segment to $\eta$ blade or its extension, measured parallel to line segment (normalized by segment length). (Fig. 17)
$L$ - LDS	Length of rotor blade outboard of flapping hinge, (ft). $L = (1 - \epsilon)R$ (Fig. 21)
$L(\eta, \psi)$ - LDS	Airloads per unit radius at radial station $\eta$ and azimuth angle $\psi$ on the $\eta$ blade, (lb/in). (Subsection 1.5.1)
$LN$ - LDS	Locke Number (ratio aerodynamic forces/inertia forces) $LN = \frac{2\pi\rho c R^4}{I_b}$
$m$ - LDS	Number of turns of the helical vortex wake used in airloads computation. Maximum age $\delta = 2\pi m$ (Fig. 5)
$m$ - WG	Number of turns of the helical tip vortex whose geometry is computed. Maximum age $\delta = 2\pi m$
$m(\bar{\eta})$ - LDS	Rotor blade running mass (slug/ft)
$M$ - WG	Number of turns of the helical vortex wake below point $P_\eta$ used in wake geometry computations. Maximum age $\delta_\ell = 2\pi(m + M)$
$M_1, M_2, M_4, M_5$ $M_6, M_7$ -LDS	Various mass and stiffness integrals over the rotor blade (Eqs. 3.132-3.137)
$M_T$ - LDS	Rotor blade tip Mach number $M_T = \frac{\text{tip speed}}{\text{sound speed}}$
$\vec{n}, \vec{n}_1$	Unit vector parallel to the contribution of a vortex line segment to the vector induced velocity at point $P_\eta$ (Fig. B1)
$n_b$	Number of rotor blades

$n_{DM}(\psi)$ - WG	Number of $\Delta\psi$ steps in the boundary age $\delta_M$ between successive boundary updates.
$n_h$ - LDS	Number of azimuthal harmonics in harmonic analysis of downwash, airloads and blade motion.
$n_\ell$	Number of radial stations $\ell_\ell$ on $\ell$ blade. For LDS-73, $n_\ell = 3$ .
$n_\delta$ - LDS	$n_\delta = (\frac{\pi}{\Delta\psi} + 1)$ - number of a stations $\delta$ used.
$n_\eta$	Number of radial stations $\eta_k$ on $\eta$ blade
$n_\psi$	Number of azimuth angles $\psi$ considered. $n_\psi = 2\pi/\Delta\psi + 1$
NFP - LDS	No Feathering Plane - no 1st harmonic feathering (rotor blade pitch rigid body pitching motion) relative to NFP (Fig. 15)
$P_a, P_b$	Endpoints of the vortex line segment (or of the front edge of the vortex sheet segment) whose contribution to the induced velocity at point $P_\eta$ is being computed. (Figs. 5, 16) (Subsection 1.5.2)
$P_c$ - LDS	Point on the tip vortex line segment (or its extension) which intersects the $\eta$ blade (or its extension) when projected into the TPP (Fig. 17)
$P_\ell$	Point on the $\ell$ blade from which an element of vortex wake is shed. (Figs. 5, 16) (Subsection 1.5.2)
$P_\eta$ - LDS	Point on the $\eta$ blade at which induced velocities and airloads are computed (Figs. 5, 16) (Subsection 1.5.2)

$P_\eta$ - WG	Point on the tip vortex at which induced velocities and wake distortion are computed (Fig. 5, 16) (Subsection 1.5.2)
$\Delta \vec{q}$ - WG	Contribution of the last wake segment ( $\delta_\eta = 0$ to $\Delta\psi$ ) to the induced velocity at point $P_\eta$ (normalized by tip speed)
$\Sigma \vec{q}$ - WG	Total induced velocity at point $P_\eta$ at age $\delta$ less the bound vorticity contribution (normalized by tip speed)
$\vec{q}_{BV}(\psi, \delta)$ - WG	Contribution of the bound vorticity to the induced velocity at point $P_\eta$ (normalized by tip speed)
$\vec{q}_{CVL}$ - WG	Contribution of a curved vortex line segment to the induced velocity vector at point $P_\eta$ , (normalized by tip speed)
$\vec{q}_D(\psi)$ - WG	Average induced velocity at point $P_\eta$ between age $\delta - \Delta\psi$ and age $\delta$ (normalized by tip speed)
$q_f$ - LDS	Close blade-vortex interaction factor for tip vortex line induced velocity computations (Subsection 3.2.4)
$\vec{q}_F(\psi, \delta)$ - WG	Contribution of far wake to induced velocity at point $P_\eta$ (normalized by tip speed)
$q_k(\eta, \psi, \zeta, \ell, \phi)$ - LDS	Contribution of the wake element identified by $\zeta, \ell$ , and $\phi$ to the z component of the induced velocity at point $P_\eta$ . (normalized by $\Gamma/4\pi R$ )
$\Delta q_k(\eta, \psi, \zeta, \ell, \phi)$ - LDS	Contribution to $q_k(\eta, \psi, \zeta, \ell, \phi)$ of tip vortex sheet segment (normalized by $\Gamma/4\pi R$ )
$q'_k(\eta, \psi, \zeta, \ell, \delta)$ - LDS	Same as $q_k(\eta, \psi, \zeta, \ell, \phi)$ but with $\delta$ explicit variable instead of $\phi$ , $\delta = \psi + \zeta - \phi$ (normalized by $\Gamma/4\pi R$ )

$\vec{q}_s$ - WG	Contribution to the induced velocity at point $P_\eta$ of all the wake from one blade with age $\delta_\ell$ (normalized by tip speed)
$q_t, q_t(\eta, \psi, \zeta, \ell, \phi)$ - LDS	Tangential component of the induced velocity contribution of a vortex line (or sheet) segment at point $P_\eta$ , (normalized by tip speed). $q_t = q_y \sin\psi - q_x \cos\psi$
$q_T, q_T(\eta, \psi)$ -WG	Tangential component of induced velocity (parallel to chord) at point $P_\eta$ , (normalized by tip speed)
$\vec{q}_{TOT}(\psi)$	If $\Sigma\vec{q}$ is labeled by its azimuth angle $\psi$ and age $\delta$ as $\Sigma\vec{q}(\psi, \delta)$ , then $\vec{q}_{TOT}(\psi) = \Sigma\vec{q}(\psi, \delta - \Delta\psi)$ , (normalized by tip speed), (Fig. 26b)
$\vec{q}_{VL}$	Contribution of a straight vortex line segment to the induced velocity vector at point $P_\eta$ , (normalized by tip speed)
$\vec{q}_{VS}$	Contribution of a vortex sheet segment to the induced velocity vector at point $P_\eta$ , (normalized by tip speed)
$q_x, q_y, q_z$	$x, y, z$ ( $\hat{i}, \hat{j}, \hat{k}$ ) components of the induced velocity contribution of a vortex line (or sheet) segment at point $P_\eta$ , (normalized by tip speed)
$q_z(\eta, \psi, \zeta, \ell)$ -LDS	$z$ component of the contribution to the induced velocity at point $P_\eta$ of the wake from radial station $\ell$ on the $\zeta$ blade. (normalized by tip speed)
QMAT( $\eta, \psi, \phi$ ) -LDS	Influence coefficient for the contribution to the $z$ component of the induced velocity at point $P_\eta$ of all wake elements at azimuth angle $\phi$ . (Subsection 3.2.1)
R	Rotor radius (ft)
$s_{1a}, s_{1b}, s_{2a}, s_{2b}$	Expressions appearing in vortex sheet segment integrals. (See Eqs. B.14 - B.17)

TPP	Tip path plane - no 1st harmonic rotor blade rigid body flapping relative to TPP (Fig. 15)
$U_p, U_p(\eta, \psi)$ -LDS	Airspeed perpendicular to NFP at point $P_\eta$ on $\eta$ blade, (normalized by tip speed). (Fig. 20)
$U_T, U_T(\eta, \psi)$ -LDS	Tangential airspeed at radial station $\eta$ and azimuth angle $\psi$ (point $P_\eta$ ) on $\eta$ blade, (normalized by tip speed). (Fig. 20)
$V_{CH}$ - LDS	Chordwise velocity in TPP at point $P_\eta$ (normalized by tip speed)
$V_R$ - LDS	Total (resultant) velocity in TPP at point $P_\eta$ - vector sum of $V_{CH}$ and $V_{SP}$ (normalized by tip speed)
$V_{SP}$ - LDS	Spanwise (radial) velocity in TPP at point $P_\eta$ (normalized by tip speed)
$V_T$ - LDS	Rotor blade tip speed (ft/sec). $V_T = \Omega R$
$w_f$	Weighting factor used in various iterations. New guess = $\omega_f$ * (latest estimate + $(1 - \omega_f)$ * (previous estimate)
$x, y, z$	Right-hand, rectangular coordinate system with origin at point $P_\eta$ . Oriented with respect to TPP (Fig. 16)
$\Delta x, \Delta y, \Delta z$	$\Delta x \equiv x_b - x_a$ , $\Delta y \equiv y_b - y_a$ , $\Delta z \equiv z_b - z_a$ (normalized by R)
$\tilde{x}, \tilde{y}, \tilde{z}$	Right-handed, rectangular coordinate system with origin at point $P_\eta$ . Oriented with respect to each individual vortex-sheet segment. (Fig. B1)
$\Delta \tilde{x}$	Length of a vortex sheet segment perpendicular to its circulation vector (normalized by R) (Fig. B3)
$x_1, x_2$	$\tilde{x}$ coordinates of forward and back edges, respectively, of vortex-sheet segment (normalized by R). (Fig. B1)

$x_a, y_a, z_a,$ $x_b, y_b, z_b$	$x, y, z$ components of $\vec{a}$ and $\vec{b}$ extending from point $P_\eta$ on the blade to endpoints $P_a$ and $P_b$ of a vortex line segment (or of the front edge of a vortex sheet segment) (normalized by $R$ ). (Fig. 16)
$x_h, y_h, z_h$	The $x, y, z$ components of $\vec{h}$ . $\vec{h} = x_h \vec{i} + y_h \vec{j} + z_h \vec{k}$ (Appendix B)
$x_x, y_x, z_x$	The $x, y, z$ components of $\vec{i}_x$ $\vec{i}_x = x_x \vec{i} + y_x \vec{j} + z_x \vec{k}$ (Appendix B)
$x_y, y_y, z_y$	The $x, y, z$ components of $\vec{i}_y$ $\vec{i}_y = x_y \vec{i} + y_y \vec{j} + z_y \vec{k}$ (Appendix B)
$z(\eta, \psi) - \text{LDS}$	Vertical displacement of point $P_\eta$ above NFP (normalized by $L$ )
$z_c - \text{LDS}$	Distance of vortex-line segment or its extension above or below $\eta$ blade (normalized by $R$ ) (Fig. 18)
$z_h - \text{LDS}$	$z$ component of distance from point $P_\eta$ to nearest point on vortex-line segment (normalized by $R$ )
$z_m$	In vortex sheet computations the mean $z$ component of vectors from point $P_\eta$ to the endpoints of the back edge of the vortex sheet (normalized by $R$ ) (Fig. B3)
$z - \text{LDS}$	Perpendicular distance from point $P_\eta$ to the vortex sheet segment (normalized by $R$ ) (Fig. B1)
$\alpha, \beta, \alpha_1, \beta_1$	Angles between the vectors $\vec{a}$ and $\vec{b}$ (from point $P_\eta$ to point $P_a$ and $P_b$ at the ends of a vortex line segment) and the vortex line segment. (Fig. A1)

$\alpha(\eta, \psi)$	Angle of attack at point $P_\eta$ - radial station $\eta$ and azimuth angle $\psi$ . (Fig. 20)
$\dot{\alpha}, \dot{\alpha}(\eta, \psi)$ - LDS	Time rate of change of angle of attack, $\dot{\alpha} = \partial\alpha/\partial\psi$
$\alpha_R$ - LDS	Reference angle of attack for dynamic stall (radians)
$\alpha_s$ - LDS	Input stall angle of attack (radians, but input in degrees)
$\alpha_{ss}$ - LDS	Computed statis stall angle of attack (radians), Eq. 3.223 or Eq. 3.224
$\gamma_o$	Constant value of bound circulation used in zeroth iteration (normalized by $2\pi b\Omega R$ ). Normally, $\gamma_o = 2(C_T/\sigma)/\pi(.8)^2$
$\gamma_a$	Vortex line (or sheet) segment circulation for constant circulation segments (normalized by $2\pi b\Omega R$ )
$\gamma_a, \gamma_b$	Vortex line (or sheet) circulation at points $P_a$ and $P_b$ , respectively, for segment having linear circulation variation (normalized by $2\pi b\Omega R$ )
$\gamma_{bv}(\psi), \gamma_{bv}(\phi)$	Bound circulation as a function of azimuth (normalized by $2\pi b\Omega R$ )
$\gamma_c(\rho), \gamma(\rho)$	Fraction of total tip vortex line circulation within $\rho$ of the center of the line (Subsection 2.4)
$\gamma_n(\eta, \psi)$ - LDS	Bound circulation from the n'th iteration at point $P_\eta$ - radial station $\eta$ and azimuth angle $\psi$ , (normalized by $2\pi b\Omega R$ )
$\gamma_s(\psi), \gamma_s(\phi)$	Shed circulation as a function of azimuth (normalized by $2\pi b\Omega R$ ) $\gamma_s(\psi) = \gamma_{bv}(\psi + \Delta\psi) - \gamma_{bv}(\psi)$
$\Gamma$	Vortex line (or sheet) segment circulation ( $\text{ft}^2/\text{sec}$ )

$\delta$ - LDS	Age of point $P_\ell$ on the wake element which was shed from station $\ell$ on the $\ell$ blade (radians) (Subsection 1.5.2)
$\delta$ - WG	Age of point $P_\eta$ on the tip vortex where $\vec{D}(\psi, \delta)$ is computed, measured in azimuth angle (radians) (Subsection 1.5.2)
$\delta_b(\phi)$	Age at which the tip vortex line segment at azimuth angle $\phi$ will experience vortex core bursting (radians) (Subsection 2.5.1)
$\delta_D$ - WG	Value of $\delta$ for the most recent computation of $\vec{D}(\psi, \delta)$ (radians)
$\delta_\ell$ - WG	Age of point $P_\ell$ on the wake element which was shed from station $\ell$ on the $\ell$ blade (radians) (Subsection 1.5.2)
$\delta_M$ - WG	Maximum value of age $\delta$ for which the distortion $\vec{D}(\psi, \delta)$ is being computed, thus the boundary between computed and assumed wake (radians)
$\delta_R$ - WG	Relative age of point $P_\ell$ measured relative to point $P_\eta$ instead of relative to the rotor (radians) $\delta_R = \delta_\ell - \delta$
$\delta_{ST}$ - WG	Initial value of $\delta_\ell$ (Fig. 26c)
$\delta_T(\zeta, \psi, k)$ - WG	Value of relative age $\delta_R$ at which a far wake/near wake or near wake/far wake transition occurs (radians)
$\epsilon$ - LDS	Rotor blade flapping hinge offset (normalized by R)
$\epsilon_s$ - LDS	Distance behind $\eta$ blade to start of near shed wake vortex sheet (normalized by R) (Subsection 2.7)
$\zeta, \zeta_i$	Azimuth angle difference between $i$ th $\ell$ blade and $\eta$ blade. For $n_b$ bladed

	rotor: $\zeta_i = (i - 1)(2\pi/n_b)$ (Figs. 5, 16) (Subsection 1.5.2)
$\eta, \eta_k$	Radial station on $\eta$ blade of point $P_\eta$ $\epsilon$ which induced velocity is computed. $\eta_1$ = inboard, $\eta_{n_\eta}$ = outboard ( $k = 1, n_\eta$ ) (normalized by R) (Figs. 5, 16) (Subsection 1.5.2)
$\bar{\eta}$ - LDS	Radial distance from flapping hinge (normalized by L), $\bar{\eta} = (\eta - \epsilon)/(1 - \epsilon)$ (Fig. 21)
$\Delta\eta$ - LDS	Radial distance from point $P_\eta$ to point $P_c$ on blade. $\Delta\eta = \eta_c - \eta$ (Fig. 17) (normalized by R)
$\eta_c$ - LDS	Radial location of passage of vortex line segment (or its extension) above or below $\eta$ blade (or its extension) (normalized by R) (Fig. 17)
$\Delta\eta_k$	Radial increment used in radial inte- grations - multiplies value of inte- grand at $\eta_k$ (normalized by R)
$\theta(\eta)$ - LDS	Rotor blade pitch angle relative to NFP (no feathering plane) at radial station $\eta$ (radians) (Fig. 20)
$\theta_o$ - LDS	Rotor blade collective pitch at zero radius (extrapolated) relative to NFP (radians)
$\theta_1$ - LDS	Rotor blade linear twist: $\theta(\eta) = \theta_o + \theta, \eta$
$\lambda$	Uniform, average downwash perpendicular to TPP - used to determine rigid wake geometry (normalized by tip speed)

$\lambda(\psi, \eta)$ - LDS	Computed downwash perpendicular to TPP at point $P_\eta$ - at radial station $\eta$ and azimuth $\psi$ , (normalized by tip speed)
$\lambda_o(\eta), \lambda_{nc}(\eta), \lambda_{ns}(\eta)$ - LDS	<p>Azimuth harmonics of <math>\lambda(\psi, \eta)</math>:</p> $\lambda(\psi, \eta) = \lambda_o(\eta) + \lambda_{1c}(\eta) \cos \psi + \lambda_{1s}(\eta) \sin \psi + \dots + \lambda_{nc}(\eta) \cos n\psi + \lambda_{ns}(\eta) \sin n\psi + \dots$
$\mu$	Advance ratio ( $V/\Omega R$ ), $V$ = flight speed (relative wind), $\Omega R$ = tip speed
$\rho$	Air density (slug/ft <sup>3</sup> ) - also: radial coordinate from the center of a vortex line (normalized by vortex-core radius $\rho_c$ )
$\rho_c$	Radius of the vortex core (normalized by $R$ )
$\rho_g$	Burst value of $\rho_c$ - vortex-core radius (normalized by $R$ )
$\rho_k$	Nonburst value of $\rho_c$ - vortex core radius (normalized by $R$ )
$\sigma$	<p>Rotor solidity: <math>\sigma = \frac{\text{rotor blade area}}{\text{rotor disk area}}</math></p> $\sigma = \frac{c_n b}{\pi R}$
$\phi$	<p>Azimuth angle of <math>\ell</math> blade, measured from same reference as <math>\psi</math></p> $\phi = \psi + \zeta - \delta$ <p>(see Figs. 5, 16) (Subsection 1.5.2)</p>
$\Delta\phi$	<p>Azimuth angle increment between successive positions of the <math>\ell</math> blade. (Azimuthal extent of trailing vortex-line segment).</p>
$\psi, \psi_j$	<p>Azimuth angle of <math>\eta</math> blade, <math>\psi = 0</math> is downstream,</p> $\psi_j = (j - 1)\Delta\psi, \quad (0 \leq \psi_j \leq 2\pi)$ <p>(Figs. 5, 16) (Subsection 1.5.2)</p>

$\Delta\psi$	Azimuth angle increment between successive positions of the $\eta$ blade
$\Omega$	Rotor angular velocity (radian/sec)

xxx

## SECTION 1

### INTRODUCTION

#### 1.1 Importance of Wake Distortion and Harmonic Airloads

Rotary winged aircraft suffer from excessive vibration. This vibration makes passengers uncomfortable, reduces crew efficiency, and induces fatigue failure in both structure and equipment. Some helicopters are at present vibration limited rather than power limited in their maximum usable speed capability. All rotary winged aircraft suffer from increased maintenance costs and reduced passenger appeal due to this excessive vibration. It is therefore important to understand and be able to predict the primary source of vibration: rotor harmonic airloads.

Rotor harmonic airloads come primarily from two sources, the once per revolution variation in velocity tangential to the blade, due to forward flight, and the rapid variations in velocity perpendicular to the blade, due to the vortex wake. Classical uniform inflow theory includes the first source of harmonic airloads, which is relatively easy to compute, but not the second, which is much more difficult to compute. Unfortunately, nonuniform inflow is the primary source of high harmonic airloads and hence vibration, so efficient nonuniform inflow computation techniques must be developed.

A complete model for the computation of the harmonic airloads, due to the nonuniform inflow induced by the vortex wake, would include: real (viscous) vortices, lifting-surface theory, compressibility, dynamic stall, and a detailed wake model with an accurate wake geometry, including the roll-up of part of the trailing vortex sheet into the tip vortex. An all-encompassing computation using such a model is impractical (i.e., it would cost too much). It is, therefore, necessary to develop an

approximate model which will reduce computation to a practical level.

The first step is to develop a better physical understanding of the various sources of harmonic airloads and their relative importance. It then becomes possible to use a very simple model for the bulk of the computation and transition to more complicated models for those areas of the wake which prove to be the most important sources of higher harmonic airloads. When constructing these models it is important to realize that most of the expense in a harmonic airloads computation is in the integration of the Biot-Savart relation over the wake to find the induced velocities at various points both in the wake and at the rotor blades. The best way to save money is, therefore, to minimize the number of elements in the wake model, the number of points at which the induced velocity is computed, and the number of times that the induced velocity at a given point due to a given wake element is recomputed.

The dominant source of rotor harmonic airloads is the rapid variation of the induced velocity at the rotor blades, both radially and azimuthally. This rapid variation is primarily due to the passage of the rotor blades close to concentrated vortices in the wake. The vortex wake is composed of the trailing wake, due to radial circulation variations, and the shed wake, due to azimuthal circulation variations. The only concentrated vortices in the wake are the tip vortices trailed from the tip of each blade. These tip vortices are due to the very rapid drop in circulation near the blade tip. Most of the trailing wake outboard of the maximum bound circulation rapidly rolls up into the concentrated tip vortex. The rest of the trailing wake and the shed wake does not roll up until it is far downstream of the rotor, if at all. The tip vortices are, therefore, the most important part of the wake and the primary source of harmonic airloads.

To compute rotor harmonic airloads, the harmonic induced

velocity at the rotor blades is computed by integration of the Biot-Savart relation over the vortex wake. To perform this integration, the location of the wake relative to the blades must be known. The location of the inboard trailing wake and the shed wake need not be known to great accuracy, since modest errors in their location do not change the induced velocity distribution very much. Due to the concentrated nature of the tip vortices, errors in their location can lead to large errors in the induced velocity distribution and hence in the harmonic airloads. Therefore, a "rigid" wake geometry based on uniform inflow is adequate for the inboard trailing wake and the shed wake, but a more accurate "distorted" wake geometry should be used for the tip vortices. The distortion is due to nonuniformities in the inflow and is computed by integration of the sum of the free stream and induced velocities over time at various points on the tip vortices.

Figure 1 is a comparison of rigid and distorted tip vortex geometries. The data is for the tip vortex of one blade of a four-bladed rotor in steady, level flight at an advance ratio,  $\mu = 0.18$ . The figure shows the geometry at the instant when the rotor blade is at an azimuth angle  $\psi = 180^\circ$ ; however, the geometry was computed for all azimuth angles  $\psi$  between  $0^\circ$  and  $360^\circ$  in  $15^\circ$  steps.

Figure 2 is a comparison of airloads computed using both rigid and distorted tip vortex geometry. Only the airloads at the 95% radial station are shown; however, 5 other radial stations were computed. The bound circulation distribution used for the tip vortex geometry computation of Fig. 1 comes from this rigid wake airloads computation. The tip vortex geometry used in the distorted wake airloads computation of Fig. 2 comes from the wake geometry computation of Fig. 1. Measured airloads from the flight tests reported in [49]\* are also shown in Fig. 2.

---

\*References are indicated by a number in square brackets [ ].

As can be seen in Fig. 1, there are substantial differences between rigid and distorted tip vortex geometries. This is especially true in the side view, where the distorted tip vortex is seen to stay in the tip path plane (TPP) until the next rotor blade arrives. This would be expected to cause dramatic changes in airloads, yet Fig. 2 shows relatively small changes. This surprising result is due to various close blade-vortex interaction effects, which tend to smooth out large airloads peaks. If these effects are neglected, there can be as much as an order of magnitude difference in airloads peak heights between rigid and distorted wake computations. These close blade-vortex interaction effects include: lifting-surface effects, tip-vortex-core effects, tip vortex core bursting, and local stall effects.

## 1.2 Previous Investigations

The ability to accurately compute helicopter rotor harmonic airloads in forward flight has steadily advanced over the last 25 years, due to the increased problems of modern, high-speed helicopters and due to the availability of high-speed digital computers. The first step beyond the classical assumption of uniform inflow was the development of theories assuming an infinite number of blades, for example [1-4]. These theories are simple enough to be used in hand computations or in tabulated solutions. These theories distribute the tip vortices from the individual blades into a single vortex cylinder leaving no concentrated tip vortices in the wake model. Therefore, such theories cannot predict high harmonic airloads, which mostly arise from close interactions between the rotor blades and concentrated tip vortices.

The next step is the utilization of high-speed digital computers. This approach permits the representation of a finite number of rotor blades where the wake of each blade is represented separately. The wake of each blade is assumed to consist of a series of vortex lines, each forming a skewed helix whose geometry

is determined by the forward speed of the helicopter (advance ratio) and the mean inflow through the tip path plane. This is the rigid wake assumption. The first of these computer solutions uses numerical integration of the Biot-Savart relation over the skewed helices [5-8]. This procedure requires a very small step size to achieve adequate accuracy. The use of infinite straight vortex lines tangent to the skewed helices at carefully selected points is found in [9,10]. This technique minimizes computation, since the Biot-Savart relation can be integrated in closed form, but accuracy is sacrificed due to neglect of the curvature of the wake. The best solution to this problem to date is the approximation of the skewed helices by a series of finite length straight vortex line segments, each subtending the same azimuth angle [10-16]. The Biot-Savart relation can be integrated in closed form over a finite straight vortex line segment. Large step sizes can, therefore, be used compared to direct numerical integration, where large step sizes result in large variations in the computed induced velocity depending on the choice of points at which the integrand is computed.

This rigid wake analysis gives a good first approximation to the induced velocity and hence the airloads due to the trailing wake. It is also necessary to include the effects of azimuthal (time) variations in circulation and the resulting shed wake. One way to do this is to use a constant average circulation in the trailing wake computations and lump all circulation variation effects into a Theodorsen lift-deficiency function [5-9]. This only accounts for circulation variations in the near wake, since it is based on two-dimensional wing theory. The far shed wake can become important when it passes under another blade or returns to pass under the original blade. To account for circulation variations in the far wake, each trailing vortex line segment is assigned a different circulation and shed vortex line segments are introduced as necessary to conserve circulation [9,14]. Instead of using a lift-deficiency function to account for near

wake effects, it is often computationally convenient to continue the integration of the shed wake up to within  $\epsilon$  of the control point on the blade, where  $\epsilon$  is determined in [9] by the condition that the result be consistent with classical theory.

As was discussed in Section 1.1, the exact location of the tip vortex relative to the blades is important in the computation of harmonic airloads. The first step beyond the rigid wake assumption is the semi-rigid wake [7,17]. This model allows each wake element to move downward (perpendicular to the tip-path plane) with its actual initial local inflow velocity at the instant it leaves the blade, instead of an average inflow velocity which is uniform over the disk. This model is better than rigid wake, but not completely satisfactory since the induced velocity experienced by any wake element changes as it moves and may even change sign. In addition, significant distortion of the wake can occur parallel to the tip-path plane as well as perpendicular to it.

The solution to these problems is to utilize a distorted (or free) wake computation in which the induced velocity vector is computed as a function of time for various wake elements and integrated to obtain the distortion vector. In a wake distortion computation, the current best estimate of the wake geometry changes as the computation proceeds. This means that both the location of the wake elements where the induced velocity vector is being computed and the geometry of the wake which induces the velocity is changing. It is, therefore, necessary to recompute or update repeatedly the integration of the Biot-Savart relation over the wake to obtain the induced velocity vectors. This is very expensive.

To reduce the amount of expensive computation, it is desirable to minimize the amount of updating. One starting point is to use an iterative scheme based on the assumption that the distorted wake geometry will not be very different from the

classical rigid wake assumption [18]. This scheme involves starting with a segment of rigid wake  $2\pi m$  in azimuth (typically,  $m = 2$ ). The rotor is then allowed to advance, generating new wake, and the distortion of this new wake is computed based on the  $2\pi m$  of the rigid wake plus the new distorted wake. No updating is used and when  $2\pi M$  ( $M \leq m$ ) of new wake has been generated, one iteration is completed. The next iteration starts using the  $2\pi M$  of distorted wake from the previous iteration, plus any extrapolation needed to fill out the  $2\pi m$  segment. This iterative process continues until satisfactory convergence is achieved. This method is cheap, since no updating is done, but it converges very slowly or not at all and it is not very accurate. This is because small changes in wake geometry can result in very large changes in the induced velocity vector for points which happen to lie near a concentrated vortex line.

To improve this situation, some updating of the induced velocity vectors must be introduced. The first step in this direction is to update the induced velocity vectors after every  $n$ th step in the computation [19]. This greatly improves both convergence and accuracy but is expensive, especially for small  $n$ . An alternative to updating every  $n$ th step is to update any given azimuth, whenever the distortion accumulated at that azimuth since it was last updated exceeds a predetermined value. This has been found to be less satisfactory than updating every  $n$  steps because it turns out that the time spent accumulating distortion due to an inaccurate induced velocity vector is more important than the amount of distortion accumulated. What sometimes happens, is that a very small amount of distortion at some azimuth, combined with the distortion of the wake inducing velocity at that azimuth, can result in a  $180^\circ$  phase change in the induced velocity vector. This phase change is not found until enough distortion is accumulated in the wrong direction to trigger a new update.

An alternative approach to computing wake geometry has been developed concurrently with the one described above [20,21]. This involves updating after every step both the induced velocity vectors and the distortion vectors for all of the wake whose distortion has been computed to date. These computations may start with either a segment  $2\pi m$  of rigid wake or with no wake at all. They continue generating new wake until a stable distortion pattern is achieved. Unfortunately, this straightforward method is very expensive, due to the large number of times that the induced velocities must be recomputed.

A major improvement over the above procedure is developed in [22]. During computation of the induced velocity at any point  $P_\eta$  on the tip vortex, the rest of the wake is divided into two parts relative to point  $P_\eta$ , the near wake and the far wake. The induced velocity at point  $P_\eta$  due to the entire wake is computed for some assumed wake geometry such as a "rigid wake". The near wake is then composed of those wake elements (straight vortex line segments) which induce at point  $P_\eta$  a velocity greater than some input value  $q_m$ . The rest of the wake becomes the far wake relative to point  $P_\eta$ . Naturally, each different point  $P_\eta$  on the tip vortex will have a different near and far wake. The induced velocity at point  $P_\eta$  due to the far wake is stored. Whenever the induced velocity at point  $P_\eta$  is updated, only the near wake contribution is recomputed, the stored value is used for the far wake. The value of  $q_m$  is a trade-off between computation time and accuracy and its selection is based on experience. This near wake technique results in about an order of magnitude reduction in computation time, which is a great improvement. There is a price for this reduction in computation time, and that is a major increase in the requirement for fast access memory capacity (core storage). This may force the use of very large interval sizes or even prohibit the use of the near wake technique, depending on the computer available.

The developments described above are primarily for the forward flight case. Hover is very different from forward flight because in hover there is no large uniform relative wind. This means that the wake does not spread out as rapidly and hence more of the wake must be considered when computing either airloads or wake geometry. It also means that induced velocities are the only velocities present and therefore wake geometry is much more sensitive to changes in induced velocity. This increased sensitivity leads to instabilities in the tip vortex geometry as shown in [23,24].

Classical propeller theory [25,26] assumes no slipstream contraction. This is adequate for axial flight, but not statically. One solution to this problem is to determine the slipstream contraction envelope based on actuator disk theory. This envelope can be used directly in an actuator disk solution for airloads [27] or as the outer boundary of the vortex sheets trailed by each rotor blade [28]. To date these envelope solutions have not produced completely satisfactory results.

Instead of the envelope approach, the distortion of the wake of each blade can be computed directly in a manner similar to the forward flight wake geometry computation methods of [19, 22]. These methods [23,29,30] still do not accurately predict the tip vortex geometry near the rotor. In the far wake, the method of [23,29] predicts instability which agrees with experimental data [23,31]. The method of [30] does not predict this instability but instead computes an average location of the wake. This is due to computing induced velocities at fixed points in space rather than at points on the wake.

Since none of the theoretical methods of computing hovering rotor wake geometry is yet completely satisfactory, an empirical correlation method has been developed based on model test data [23,29,31,32]. This correlation method is currently the most useful method of computing hovering rotor wake geometry. It

is limited to relatively conventional rotors at present and a better theoretical model is still desirable.

This quick survey of previous investigations is intended to place the current work in the context of previous and parallel efforts in this field. A more general survey of the literature can be found in [33].

### 1.3 Current Investigation

The concentrated tip vortices are the primary source of vibratory rotor airloads. It is, therefore, necessary to be able to compute tip vortex geometry as a part of an accurate vibratory airloads computation. Methods have been developed for computing tip vortex geometry, but they are very expensive. The current investigation therefore concentrates on developing inexpensive tip vortex geometry computation techniques with provisions for trading-off accuracy for cost. In addition, an efficient airloads computation is developed, both to provide the circulation distribution as an input to the tip vortex geometry computation and to determine the effect of tip vortex geometry on harmonic airloads. The special case of hovering rotor tip vortex geometry is also studied.

#### 1.3.1 Wake Models

The first step is the development of the simplest mathematical model for the vortex wake which gives acceptable results. The wake is divided into three parts: the tip vortex, the inboard trailing wake, and the shed wake. Models are developed for each of these parts. These models are made up of straight vortex line segments, curved vortex line segments, and plane rectangular vortex sheet segments. These segments can either be of uniform circulation strength or they can have a linear variation in circulation strength. The vortex line segments have a vortex core in which viscous effects become important. In some cases, vortex line segments having an artificially large vortex core are used to

represent vortex sheet segments at a considerable saving in computation time.

A basic wake model is developed. The tip vortex is represented by a vortex line made up of straight vortex line segments. Curved vortex line segments are used for those segments of tip vortex, adjacent to the point  $P_\eta$  on the tip vortex, at which the induced velocity is being calculated during a wake geometry computation. The inboard trailing wake is represented by either a vortex sheet or by a vortex line having an artificially large vortex core. The shed wake can be represented by either a series of vortex sheet segments or by a series of vortex line segments having artificially large vortex cores. In any case, the near shed wake is represented by a vortex sheet segment extending to within a distance  $\epsilon$  of the control points on the rotor blade. This basic wake model and various refinements of it are discussed more fully in Section 2.

Due to the lack of relative wind, the wake models used in the computation of hovering tip vortex geometry are somewhat different from those for forward flight. This is discussed further in Section 1.3.5.

#### 1.3.2 Circulation-Wake Geometry Iteration

For the forward flight case, two separate computer programs have been developed: one for computing tip vortex geometry and one for computing rotor airloads. The airloads program (LDS) uses a given tip vortex geometry which is held constant for the duration of the computation. This geometry can be either a "rigid wake" geometry based on a uniform inflow or a distorted geometry computed by the tip vortex geometry program. The tip vortex geometry program (WG) uses a circulation distribution which remains unchanged for the duration of the computation. This circulation distribution is normally obtained from a previous run of the airloads program. As shown in Fig. 3, these two programs are normally run together in a circulation distribution,

tip-vortex geometry iteration. The first step in this iteration is usually an airloads computation using the "rigid wake" tip vortex geometry. Tip-vortex geometry is generally not very sensitive to moderate variations in the circulation distribution. Thus one iteration involving an initial "rigid wake" airloads computation, a wake geometry computation, and a final "distorted wake" airloads computation is usually sufficient.

### 1.3.3 Tip Vortex Geometry Computation

The method of computing tip vortex geometry is an extension and refinement of the method developed in [19]. The modifications fall into two categories: those which increase accuracy at the expense of some increase in computation time and those which greatly reduce the computation required with a minimal sacrifice in accuracy. The net result is a method which uses the basic iterative approach of [19], but has been completely reworked to achieve both increased accuracy and a reduction in the amount of computation required.

The major saving in computation comes from the adoption of a near-wake/far-wake scheme similar to that used in [22]. Such a scheme was considered during the development of the method reported in [19]. The scheme was rejected because it required more fast access computer memory (core storage) than was available at M.I.T. at that time. The publication of [22] inspired a second look at the problem to find a way of reducing the core storage requirements to a level practical for use on the available computer. The result is a near-wake/far-wake scheme which achieves most of the savings in computation obtained in [22] with a much more modest core storage requirement. This scheme is described in Section 4.

In [19] only the induced velocities at points on the boundary between the "new" wake, whose geometry has been computed during the current iteration, and the "old" wake, whose geometry has not been computed yet, are updated. This form of updating has

been retained, with the refinement that the frequency of updating is a function of azimuth. This allows more frequent updating to be specified at the sides, where many different tip vortices interact closely, compared to fore and aft, where the tip vortices are more spread out.

In addition, a second, more complete type of updating has been introduced. In this case, induced velocities are updated for all of the "new" wake, not just the points on the boundary. This type of updating requires computation of the induced velocity at many more points than the first type of updating and it is done much less frequently. The use of this second type of updating requires a substantial increase in the amount of computation. On the other hand, it improves the accuracy and stability of the wake geometry computation, reducing the number of iterations required and improving the accuracy of the results. Fortunately, the saving in computation achieved by using the near-wake scheme more than compensates for the extra computation required by the new updating process.

In addition to the major modifications to the methods of [19] described above, various refinements have been introduced. Instead of basing the wake geometry on only the most recent computation of the distortion, at each stage in the computation the latest computation of the incremental distortion during the latest step in age (time) is combined with the immediately preceding computation of the same distortion in a weighted average. This averaging greatly improves the stability and the convergence of the tip-vortex geometry computation. Another refinement is the use of closed-form integration of the induced velocity over time to compute the distortion due to the bound vorticity when a rotor blade passes over an element of the tip vortex. This avoids the problem of sampling the induced velocity due to the bound vorticity at discrete points in an area of rapid variation.

In summary, a new tip-vortex geometry-computation method has been developed starting from the method of [19]. The major developments are:

- (a) The use of more sophisticated wake models using vortex sheets, vortex lines having artificially enlarge vortex cores, and vortex core bursting.
- (b) The near-wake/far-wake scheme.
- (c) Modification of the original type of updating and the addition of a new type of updating.

In addition, various lesser developments have been introduced. For a more detailed account of these developments, see Section 4.

#### 1.3.4 Harmonic Airloads Computation

As shown in Section 1.3.2, an airloads computation is needed to supply the circulation distribution to the wake geometry computation. It must also be remembered that the actual goal is the improved computation of rotor harmonic airloads, not just the computation of tip-vortex geometry. Thus an airloads computation is necessary to evaluate the effects of tip-vortex geometry on rotor airloads.

To these ends an airloads computation has been developed. It is described in detail in Section 3, so only its more important or unusual features will be outlined here.

- 1) The wake models used are generally similar to those used in wake-geometry computations.
- 2) There is provision for a jump in tip-vortex-core size after a close blade-vortex interaction.
- 3) The "rigid-Wake" geometry is always used for the in-board portion of the wake and can be used for the tip vortex. Alternatively, the distorted tip-vortex geometry obtained from a wake-geometry computation can be used.

- 4) Normally, lifting-line theory is used but for close blade-tip-vortex interactions, lifting-surface theory is used.
- 5) Radial flow, dynamic stall, and some compressibility effects are represented by simplified models.
- 6) Rigid-body flapping and first mode blade bending (with an assumed mode shape) are included in the blade-motion solution. No lag or torsional motion of the blade is included. Flapping hinge offset is included and a spring restraint about the flapping hinge can be used to represent "rigid" rotors.

The computation of airloads with distorted tip-vortex geometries, using the above techniques, demonstrated that the methods for computing close blade-tip vortex interactions are inadequate. This lead to experiments with various models of the interaction process. These experiments have lead to some rather crude, empirical models which give somewhat better results. They also demonstrate the critical importance of close blade-tip vortex interactions in determining the harmonic airloads and the necessity for basic research in this area. Until a better model for close blade-tip vortex interactions is available, the computation of accurate tip-vortex geometries, at considerable expense, is hard to justify, except in special cases such as hover.

#### 1.3.5 Hovering Wake Geometry

The hovering tip-vortex geometry computation is developed from the general forward-flight computation. Axial symmetry of the wake geometry is assumed (i.e., any wake element having a given radial station  $\eta$  and age  $\delta$  will have the same geometry for all azimuth  $\psi$ ). This symmetry assumption greatly simplifies the computation, since tip-vortex geometry and hence induced-velocities

are calculated at only one azimuth instead of at twenty-four azimuths.

Since there is no relative wind in the hovering case, the wake does not move away from the rotor as rapidly as in the forward flight case. This requires that a hovering tip-vortex-geometry computation consider more of the wake than a forward flight computation. Typically  $12\pi$  (6 turns) of hovering tip vortex geometry is computed and as much as  $24\pi$  (12 turns) of wake is considered below point  $P_\eta$  when computing the induced velocity at that point. In addition, a semi-infinite vortex cylinder is used to represent the tip vortex from the end of the normal wake model to infinity. Besides the normal models used to represent the inboard trailing wake, there is provision for the use of tilted vortex sheets based on the experimental observations of [23].

A specialized airloads computation for the hovering case has not been developed. Due to the assumption of symmetry, the circulation is constant around the azimuth. The tip vortex circulation used in tip vortex geometry computations is obtained either by simple uniform inflow computations or from the experimental data. This is adequate for current use but an operational hovering tip-vortex geometry computation would require a corresponding airloads computation.

The results obtained from the hovering tip-vortex geometry computation near the rotor are similar to those obtained by other investigators [23,30] making similar computations (i.e., the theory does not predict rapid enough wake contraction or downward movement near the rotor). In the far wake, convergence to a stable tip-vortex geometry is achieved only by the introduction of weighted averaging between iterations as described in Section 1.3.3. This convergence may be artificial and only represents an average position of the tip vortex, since there is some evidence that the far wake is unstable in reality [23,24].

#### 1.4 Assumptions and Approximations

This section is a review of the basic assumptions and approximations used in the computation of tip-vortex geometry and harmonic airloads. The basic assumption of steady state, equilibrium flight is made. This means that the rotor angular velocity  $\Omega$ , the helicopter flight speed (or the relative wind speed)  $V$ , the incidence of the tip-path plane relative to the wind,  $i$ , and the net thrust and torque of the rotor all remain constant over time. It is further assumed that all rotor-blade referenced quantities such as airloads, bound circulation, and blade motion are cyclic in azimuth angle every  $360^\circ$ . This implies that the wake circulation is also cyclic every  $360^\circ$  and that the wake geometry is stable.

A simplified basic model is used to save computation. This basic model can be described as unsteady, three-dimensional, inviscid and incompressible lifting-line theory. This basic model is satisfactory for the bulk of the computations, but is modified in some regions. Near a concentrated vortex line, such as the tip vortex, a special vortex-core model is used. Viscous effects such as stall and tip vortex core bursting are also modeled. Compressibility effects on lift-curve slope, on maximum lift coefficient, and on drag are included. For close rotor-blade/tip-vortex interactions, lifting-surface theory is used. Thus the more important effects of viscosity, compressibility, and lifting-surface theory are included without the expense and complication of using a complete viscous and compressible lifting-surface theory.

A set of formulae is used to approximate airfoil section lift and drag as a function of Mach number, angle of attack and time rate of change of angle of attack. These formulae are typical of modern cambered helicopter airfoils, but do not represent any particular airfoil. Dynamic stall, radial flow, and reverse flow effects are modeled. The tangential component of induced

velocity can be included if desired, but it is not normally very important.

In the blade-motion solution, rigid-body flapping and first mode flapwise blade bending are included, but lag and torsional motion are not. The effects of flapping hinge offset are included but lag and torsional motion are not. The effects of flapping hinge offset are included and a spring about the flapping hinge can be used to simulate a cantilever rotor. In both the calculation of blade motion and of harmonic airloads, all harmonics of blade motion are included and no small angle assumptions are made. In the determination of the relative positions of the wake and the rotor blades, however, the zeroth and first harmonics of flapping are assumed to be small angles and the higher harmonics of flapping plus all harmonics of blade bending are neglected.

## 1.5 Nomenclature and Notation

### 1.5.1 Fundamental Nomenclature

This section defines the most important nomenclature used in this report. Less important, or less widely used nomenclature will be defined where it is first used. To start with fundamentals, consider the words: airloads (or harmonic airloads), wake geometry, and distortion.

Airloads are the rotor blade section aerodynamic lift per unit radius (lb/in). The lift is that component of the total section aerodynamic force which is perpendicular to the local relative wind (neglecting radial flow). Airloads vary with both the rotor blade azimuth angle ( $\psi$ ) and the radial station ( $r$ ) on the rotor blade. The term harmonic airloads is used to emphasize that all azimuthal harmonics of airloads are of interest here, not just the steady-state component.

Wake geometry is the geometric relationship between the various elements of the wake and of the rotor. All wake geometry

is measured relative to the rotor tip-path plane (TPP). This eliminates the effect of first harmonic flapping on wake geometry. The effects of higher harmonics of flapping on wake geometry are neglected.

The wake geometry is divided into two parts: the fundamental wake geometry and the distortion. The fundamental wake geometry is that due to the motion of the rotor blades relative to the free stream (neglecting higher harmonic flapping). Thus the fundamental tip-vortex geometry is the skewed helix described by the rotor blade tip as it moves relative to the free stream. The distortion is that part of the wake geometry which is due to the velocities induced by the wake and by the bound circulation. In the "rigid wake" assumption, the induced velocity is uniform and perpendicular to the TPP. Thus, for this case, the tip vortex distortion is obtained by adding the uniform induced inflow to that component of the free stream which is perpendicular to the TPP. This results in the stretching of the fundamental skewed helix along an axis perpendicular to the TPP.

In the general distorted wake case, the induced velocity can be nonuniform, time varying, and three dimensional. Consider the location of a general point  $P_\ell$  in the wake. Point  $P_\ell$  will have a position ( $P_\ell^F$ ) on the fundamental skewed helix which remains fixed relative to the air in the free stream. The distortion vector ( $\vec{D}$ ), drawn from  $P_\ell^F$  to the actual location of point  $P_\ell$ , will, in general, vary with time and with the choice of point  $P_\ell$ .

#### 1.5.2 Fundamental Notation

This section defines the basic notation needed to follow the more general portions of this report. Other, less important notation is defined as it first occurs in the text. Most of the notation used here is defined in an alphabetical list of notation at the beginning of this report. Any notation not defined in

this list is very specialized and is only used in one small part of the report, such as an appendix.

Point  $P_\eta$  is a general point at which the induced velocity is being computed. For airloads computations,  $P_\eta$  is a point on the  $\eta$  blade of the rotor. The  $\eta$  blade has an azimuth angle  $\psi$  and point  $P_\eta$  is at radial station  $\eta$ . Radial station  $\eta$  is a distance  $\eta R$  from the center of rotation, where  $R$  is the rotor radius.

For wake geometry computations,  $P_\eta$  is a point in the wake. The element of wake at point  $P_\eta$  was originally shed from radial station  $\eta$  on the  $\eta$  blade, which had an azimuth angle  $\psi$  at the instant of shedding. The current age  $\delta$  of the element of wake at point  $P_\eta$  is the difference between  $\psi$  and the current azimuth angle of the  $\eta$  blade. Thus the azimuth angle, in radians, is used as a nondimensional time. Figure 4 illustrates the case  $\psi = 60^\circ$ ,  $\eta = 1.0$ ,  $\delta = 180^\circ$ ,  $\mu = 0.19$ , and  $\Delta\psi = 30^\circ$ , where  $\mu$  is the advance ratio (relative wind speed normalized by tip speed) and the tip vortex line is represented by straight line segments subtending  $\Delta\psi = 30^\circ$ .

Point  $P_\ell$  is the point at the upper (larger azimuth angle) end of the vortex-line segment whose contribution to the induced velocity at point  $P_\eta$  is being computed. The element of wake at point  $P_\ell$  was originally shed from radial station  $\ell$  on the  $\ell$  blade, which had an azimuth angle  $\phi$  at the instant of shedding. The current age,  $\delta_\ell$ , of the element of wake at point  $P_\ell$  is the difference between  $\phi$  and the current azimuth angle of the  $\ell$  blade. On a multi-bladed rotor the  $\ell$  blade and the  $\eta$  blade are not always the same. The  $\ell$  blade is identified by  $\zeta$ , which is the azimuth angle by which the  $\ell$  blade leads the  $\eta$  blade. Thus, for a three-bladed rotor,  $\zeta$  can have three values:  $0^\circ$ ,  $120^\circ$ , and  $240^\circ$  associated with the three blades. For example, in Fig. 4,  $\zeta = 0$  and in Fig. 5,  $\zeta = 120^\circ$ .

Figure 5 illustrates the case of a three-bladed rotor ( $n_b = 3$ ),  $\mu = .19$ ,  $\eta = .50$ ,  $\ell = 1.0$ ,  $\psi = 120^\circ$ ,  $\delta = 0^\circ$ ,  $\phi = 150^\circ$ ,

$\Delta\phi = 30^\circ$ ,  $\delta_\ell = 90^\circ$ ,  $\zeta = 120^\circ$ , and  $m = 2$ , where  $\Delta\phi$  is the vortex line segment size and  $m$  is the number of turns ( $360^\circ$  in azimuth) of wake included. Only the tip vortex of the  $\zeta = 120^\circ$  blade is shown for clarity. The  $\ell$  blade is shown at three different ages: 0,  $\delta_\ell$ , and  $\delta_\ell + \Delta\phi$  while the  $\eta$  blade is only shown at age  $\delta = 0$ .

Notice that the age  $\delta_\ell$  is related to  $\zeta$ ,  $\psi$ , and  $\phi$ :

$$\delta_\ell = \psi + \zeta - \phi \quad (1.1)$$

For wake geometry computations  $\delta$  is not zero at points  $P_\eta$  in the wake and Eq. 1.1 can be generalized:

$$\delta_\ell = \psi + \zeta + \delta - \phi \quad (1.2)$$

For airloads computations, however,  $\delta$  is always zero, since the induced velocity is only computed at points  $P_\eta$  on the rotor blades. Since  $\delta$  is not needed for the age of  $P_\eta$  in airloads computations, it is normally used to replace  $\delta_\ell$ , the age of  $P_\ell$ , in these computations. Thus the  $\delta$  used in wake geometry computations is always zero in airloads computations and the  $\delta_\ell$  used in wake geometry computations becomes  $\delta$  in airloads computations. This means that Eq. 1.2 applies only to wake geometry computations and that, for airloads computations, Eq. 1.1 becomes:

$$\delta = \psi + \zeta - \phi \quad (1.3)$$

The points at the ends of the vortex-line segment, whose contribution to the induced velocity at point  $P_\eta$  is being computed, are labeled points  $P_a$  and  $P_b$ . Normally, point  $P_a$  is also point  $P_\ell$ . The vectors from point  $P_\eta$  to points  $P_a$  and  $P_b$  are  $\vec{a}$  and  $\vec{b}$ , respectively. The nondimensional circulation of the vortex-line segment is  $\gamma_a$ , with positive  $\gamma_a$  going from point  $P_a$  to point  $P_b$ . Figure 5 illustrates these definitions.

The airload at point  $P_\eta$  on the  $\eta$  blade is  $L(\eta, \psi)$ , with dimensions of lb/in. The local blade section angle of attack

at point  $P_\eta$  on the  $\eta$  blade is  $\alpha(\eta, \psi)$  radians. The total inflow, perpendicular to the TPP, at point  $P_\eta$  on the  $\eta$  blade is  $\lambda(\eta, \psi)$ , normalized by tip speed ( $\Omega R$ ). The distortion vector of a point  $P_\eta$  on the tip vortex is  $\vec{D}(\psi, \delta)$ , normalized by rotor radius ( $R$ ). Note that if point  $P_\eta$  is not constrained to be on the tip vortex, then  $\vec{D}$  also becomes a function of the radial station  $\eta$ .

Since only steady-state flight is considered here, airloads, inflow, blade motion, etc., repeat every  $2\pi$  in azimuth. It is, therefore, often convenient to harmonically analyze these quantities. For most variables, the harmonics are written conventionally. For example, airloads:

$$L(\eta, \psi) = L_o(\eta) + \sum_{n=1}^{\infty} \left[ L_{nc}(\eta) \cos(n\psi) + L_{ns}(\eta) \sin(n\psi) \right] \quad (1.4)$$

and inflow, positive downwards:

$$\lambda(\eta, \psi) = \lambda_o(\eta) + \sum_{n=1}^{\infty} \left[ \lambda_{nc}(\eta) \cos(n\psi) + \lambda_{ns}(\eta) \sin(n\psi) \right] \quad (1.5)$$

For the rotor-blade flapping angle  $\beta(\psi)$ , positive upwards, the NACA notation is used:

$$\beta(\psi) = a_o - \sum_{n=1}^{\infty} \left[ a_n \cos(n\psi) + b_n \sin(n\psi) \right] \quad (1.6)$$

The flapping is measured relative to the no-feathering plane (NFP), since there is no first harmonic flapping relative to the TPP.

### 1.5.3 Normalization

Most of the variables used in this report are nondimensional (normalized). Table 1 summarizes the general rules used in normalizing variables. Exceptions to these rules will be explained as they occur in the rest of the report. Standard helicopter normalization is used for advance ratio  $\mu$ , thrust coefficient  $C_T$ , horizontal force coefficient  $C_H$ , power coefficient  $C_P$ , torque coefficient  $C_Q$ , and solidity  $\sigma$ .

## SECTION 2

### VORTEX-WAKE MODELS

Any scheme to compute either wake induced airloads or wake geometry must start with a mathematical model of the wake. As discussed previously, this model must be as simple as possible to allow efficient computation of induced velocities. The Biot-Savart relation (for large distances) is such that the magnitude of the induced velocity varies inversely with the square of the distance between a finite element of vortex wake and the point at which the induced velocity is computed. Therefore, when computing the induced velocity at a point  $P_\eta$ , the wake near point  $P_\eta$  must be treated very carefully. The wake moderately far from point  $P_\eta$  can be represented by relatively simple models and the wake very far from point  $P_\eta$  can be neglected. The Biot-Savart relation also implies a singularity in induced velocity at the center of any vortex wake element having finite circulation. Since there are no infinite induced velocities in reality, the mathematical model of the vortex wake must include physically realistic ways of avoiding these singularities.

#### 2.1 Basic Wake Model

First, the basic wake model must be chosen. This consists of a concentrated tip vortex line, an inboard trailing vortex line or sheet, and a shed wake. The trailing wake is the wake resulting from radial variations in the bound circulation, while the shed wake comes from azimuth bound circulation variations. As discussed in Subsection 1.1, the tip vortex is the most important part of the wake and must be represented in any wake model. The inboard trailing wake is necessary to conserve circulation. Trial runs show that airloads and wake geometry computations made both with and without it included, give substantially different results (Fig. 6). If the trailing wake circulation is constant around the azimuth, then

there is no shed wake. If the trailing-wake circulation varies around the azimuth, then there must be a shed wake to conserve circulation.

To extend the basic wake model all the way to infinity would require an infinite amount of computation, which is not practical. The following approximations are, therefore, used. For hovering cases, the basic wake model extends downward for about one rotor radius, and thereafter the tip vortex is represented by a semi-infinite vortex cylinder over which the Biot-Savart relation can be integrated in closed form. For forward-flight cases, enough revolutions of wake are included in the basic wake model to ensure that it contains all wake elements within about a rotor radius of any point at which induced velocities are computed. This is, typically, four revolutions for  $\mu = 0.10$  or two revolutions for  $\mu = 0.20$ . The rest of the wake is neglected, since it makes a negligible contribution to the induced velocities being computed. Figure 7 shows two revolutions of the basic wake model.

## 2.2 Wake Model with n Trailing Vortex Lines

The question of more elaborate wake models than the basic one described above requires some discussion. The standard technique is to use a multiplicity of trailing vortex lines, typically 10 to 20. To determine the wake circulation, it is necessary to find the induced velocity, and hence, the circulation at  $n-1$  radial stations for an  $n$  trailing vortex-line-wake model. When the basic wake model is used, the induced velocity can be computed at any convenient number of radial stations, typically six, which results in a factor of 1.5 to 3 saving in computation. The lesser number of wake elements in the basic wake model results in a further factor of 6 to 13 saving in computation time.

To avoid the very time-consuming, repeated computation of induced velocities by the Biot-Savart relation during airloads computations, a matrix of influence coefficients (QMAT) is stored.

When QMAT is multiplied by a bound circulation matrix, a matrix of the induced velocity at each radial and azimuthal station is produced. QMAT is only a function of wake geometry and the wake model used; thus it remains constant during the complete circulation iteration. The size of QMAT is determined by the number of induced velocities computed (number of radial stations times the number of azimuthal stations, typically  $6 \times 25 = 125$ ) and by the size of the bound circulation matrix (the number of radial stations times the number of azimuthal stations, typically  $1 \times 25 = 25$ ). In the basic wake model, only one radial bound circulation station is required to completely describe the wake model. Thus, at 4 bytes per word, QMAT requires about 15k bytes of core storage. When compared to the 180k bytes required by the entire airloads program, this is not excessive. For the  $n$  trailing vortex-line case,  $n-1$  radial bound circulation stations are needed. Thus, for  $n=20$ , about 930k bytes of core storage is needed, which is more than 5 times the size of the rest of the airloads program. Thus, to save both computation time and computer core storage, effort has been concentrated on the basic wake model and simple extensions which only require one radial bound circulation station.

### 2.3 Wake Model Elements

It is not possible to integrate the Biot-Savart relation for induced velocity in closed form over the relatively simple "rigid wake" geometry, much less over the actual distorted wake geometry. This leaves a choice between numerical integration over the actual shape of the wake or the construction of an approximate wake model out of simple elements for which the Biot-Savart relation can be integrated in closed form. In the first case, errors arise from the computation of the integrand at discrete points in an area of rapid variation. These errors become large near a concentrated vortex line, such as the tip vortex, unless the number of integrand computation points is made very large. In the second case, errors arise from the representation of curved vortex line elements by a series of straight line segments. These errors are acceptable

for reasonable line-segment lengths (typically  $15^\circ$  in azimuth). For a given level of accuracy, the second case requires much less computation than the first and it is, therefore, used hereafter.

The simple wake elements chosen are straight vortex-line segments, plane rectangular vortex sheet segments, and circular arc vortex-line segments. Formulas are developed in Appendix A for the velocity induced, at a general point in space, by straight vortex-line segments having either constant circulation or a linear variation of circulation. Similar formulas are developed in Appendix B for plane rectangular vortex sheets. Formulas are developed in Appendix C for the velocity induced by a circular arc vortex-line segment (with a finite vortex core) at a point on itself. The self-induced velocity of a circular arc vortex-line segment is infinite unless a vortex core, where the circulation is a function of radius, is included in the computation. The actual use of these elements to model the various parts of the wake is described below, in Subsections 2.5, 2.6, and 2.7.

## 2.4 Vortex Core Models

Three different vortex core models are used for vortex-line segments. One of these models is also used for vortex sheet segments. All of these models assume that the vortex core is axially symmetric about the center of the vortex line. The size of the core region is characterized by a core radius  $\rho_c$  (normalized by  $R$ ). This parameter  $\rho_c$  is defined as the radius at which the maximum tangential induced velocity is achieved. Thus  $\rho_c$  is not necessarily the radius at which the vorticity goes to zero or the outer limit of the region where the Biot-Savart relation is inaccurate.

### 2.4.1 Solid Body Rotation Model

The simplest vortex core model is solid body rotation. For this case, the radial circulation distribution is:

$$\gamma_c(\rho) = \begin{cases} \rho^2, & 0 \leq \rho \leq 1 \\ 1.0, & \rho \geq 1 \end{cases} \quad (2.1)$$

where  $\gamma_c(\rho)$  is the circulation at radius  $\rho$  (normalized by the total circulation of the vortex line) and  $\rho$  is the radial coordinate from the center of the vortex line (normalized by  $\rho_c$ ). This model considerably overestimates the induced velocity near  $\rho = 1.0$  and hence it is not used here for straight vortex-line or vortex-sheet segments. Bliss [40] shows that the choice of circulation distribution makes very little difference when computing the self-induced velocity of a vortex ring. The simple solid body rotation model is, therefore, used here for curved vortex-line segments which are simply incomplete vortex rings.

#### 2.4.2 Fixed Wing Vortex Core Model

A somewhat more complicated model is the "fixed wing vortex core model". This model is based on measurements of tip vortex properties behind fixed-wing wind-tunnel models [36, 37, 38]. The vortex core radius is:

$$\rho_c = .05 (c/R) \quad (2.2)$$

where  $c$  = blade chord (ft). The radial circulation distribution is:

$$\gamma_c(\rho) = \frac{\rho^2}{1 + \rho^2} \quad (2.3)$$

In the experimental data [36, 37, 38],  $\rho_c$  varies from 0.025 ( $c/R$ ) to 0.063 ( $c/R$ ) and the peak tangentially induced velocity varies from 84% to 139% of that predicted by this model. From Eq. 2.3,  $\gamma_c(1) = 0.5$  for this model and from Eq. 2.1  $\gamma_c(1) = 1.0$  for the solid body rotation model. Thus, the solid body rotation model gives twice the peak tangential induced velocity that this model does and therefore does not agree as well with the experimental data.

This fixed-wing vortex-core model is very easy to use.

For the case of a straight vortex-line segment:

$$\rho = h / \rho_c \quad (2.4)$$

where  $h$  is defined in Eq. A.19 of Appendix A. Now  $\gamma_c(h)$  can be written:

$$\gamma_c(h) = \frac{h^2}{h^2 + \rho_c^2} \quad (2.5)$$

To obtain the induced velocity contribution of a straight-line vortex segment, including a vortex core, the normal expression developed in Appendix A is multiplied by  $\gamma_c(h)$ . The case of a vortex-sheet segment is more complicated because  $\gamma_c(h)$  is a function of  $x$  and is inside the  $x$  integral. This case is discussed in Subsection B.3 of Appendix B.

#### 2.4.3 Rotary Wing Vortex Core Model

Recently, Cook [39] has published measurements of the tip vortex of a full-scale, one-bladed helicopter rotor hovering on a whirl tower. These measurements show almost an order of magnitude smaller core radius  $\rho_c$  when compared with the fixed-wing measurements [36, 37, 38]. The magnitude of the measured peak tangentially induced velocity is about the same. This implies a very different type of radial circulation distribution and a new "rotary-wing vortex core model" has been developed to fit this data. The vortex-core radius is:

$$\rho_c = .008 (c/R) \quad (2.6)$$

and the radial circulation distribution is:

$$\gamma_c(\rho) = \begin{cases} 0.2 \rho^2 / (1 + \rho^2) & , 0 \leq \rho \leq 1 \\ 1.0 - 0.9 e^{-.075(\rho-1)} & , \rho \geq 1 \end{cases} \quad (2.7)$$

This model is only used for straight vortex-line segments. The model is not used for vortex sheets because there are no measurements available for vortex sheets behind a rotor blade. In the absence of experimental data, the "fixed-wing vortex core model",

which is much easier to integrate, is used for vortex-sheet segments.

#### 2.4.4 Comparison of Vortex Core Models

A comparison of the induced velocity ( $V_\theta$ ) as a function of the radial coordinate ( $\rho$ ) for the three different vortex-core models is given in Fig. 8. The results are normalized by the peak induced velocity of the solid body rotation model ( $V_\theta^*$ ). The core size  $\rho_c$  for the solid body rotation and the "fixed-wing" models is the same and is used to normalize the  $\rho$  in Fig. 8. The  $\rho_c$  for the "rotary-wing" model is only 15% as large as the  $\rho_c$  for the other two models. The smaller core size is a necessary part of the model.

For the solid body rotation model, the influence of the vortex core ends at  $\rho = 1$  and everything after that is simply the Biot-Savart relation. For the other two models, the influence of the vortex core extends to infinity. As can be seen in Fig. 8, the results of both of these models are asymptotic to the Biot-Savart relation for large  $\rho$ . Therefore, the computation of the vortex core influence can be dropped for sufficiently large  $\rho$ .

As shown in Fig. 8, the fixed-wing model gives about the same results as the rotary-wing model, except for  $\rho < 0.5$  (i.e.,  $\rho < 0.025$  chords). Since such close blade-vortex interactions do not occur very frequently, airloads computations using the two different models normally give similar results (see Fig. 9). As shown in Appendix D, there is some doubt about the validity of the rotary-wing model. Based on these considerations, and the great simplicity of the fixed-wing model, the rotary-wing model remains experimental while the fixed-wing model is standard. For more background on the fixed- and rotary-wing vortex-core models, see Appendix D.

## 2.5 Tip Vortex Models

The concentrated tip vortex line is (with one exception) represented by straight vortex-line segments subtending equal azimuth intervals ( $\Delta\phi$ , typically  $15^\circ$ ). The exception occurs when it is necessary to compute the induced velocity at a point on the tip vortex line, due to the adjacent tip vortex-line segments. This occurs only in the tip vortex geometry program. For this case, curved vortex-line segments are used, Appendix C. Whether curved or straight, vortex-line segments have vortex cores. For curved segments, the solid body rotation vortex core model is used. For straight segments, the fixed-wing vortex-core model is normally used, but the rotary-wing vortex-core model is available as an option.

### 2.5.1 Vortex Core Bursting

A close interaction between a rotor blade and a concentrated tip vortex line may cause changes in the properties of the tip vortex line. One possibility is that a close blade-vortex interaction will cause instability in the viscous vortex core leading to a breakdown or bursting of the core. This bursting does not destroy circulation, but does result in a large increase in vortex-core radius.

Another possibility is the interaction of the concentrated tip vortex line and the near wake. A close blade-vortex interaction generates rapid spanwise variations of bound circulation on the rotor blade (Fig. 10). These variations lead to a trailing wake near the blade known as the near wake. The central portion of the near wake comes from the very rapid change of bound circulation between the positive and the negative peaks shown in Fig. 10. This central portion is relatively concentrated, has circulation opposite in sign to the tip vortex line, and can be of the same order of magnitude as the tip vortex line. The outer portions of the near wake are spreadout vortex sheets having the same total magnitude of circulation as the central portion, but of opposite sign. Thus,

the central portion of the near wake could roll up with the tip vortex line and partially cancel it, leaving the distributed outer portions instead. This process should be modeled by reducing the tip vortex-line circulation and adding vortex sheets on either side of the vortex line. This is complicated. A crude, but much simpler model, is to increase the vortex-core radius.

To explore the effect of these possibilities on airloads and wake geometry, a vortex-bursting model has been developed. Two vortex-core radii are used for the concentrated tip vortex line: a small radius associated with the vortex-core model and a much larger, burst radius. All tip vortex-line segments start out with the small radius when they leave the blade at zero age. If the tip vortex-line segment at azimuth angle  $\phi$  experiences, for the first time, a close blade-vortex interaction at age  $\delta_b$ , it is said to have burst. This segment at  $\phi$  will then have the small radius for all ages less than  $\delta_b$  and the larger, burst radius for all ages greater than  $\delta_b$ . This  $\delta_b(\phi)$  function is obtained routinely during airloads computations and can be input for wake geometry computations. The criteria for determining if a blade-vortex interaction is close enough to cause bursting and at what point in the interaction this bursting occurs are input parameters. These parameters and the vortex-core radii can be varied to test different theories.

Observation of measured rotor airloads [49,50] shows that close blade vortex interactions near  $\phi = 90^\circ$  normally produce larger airload peaks than similar interactions at larger azimuth angles. Ordinary vortex bursting is not the answer, because these peaks often come from the first close interaction that a particular tip vortex-line segment experiences. These first interactions are due to a rotor blade sweeping over the tip vortex line left by the preceding blade, starting at about  $\phi = 90^\circ$  and continuing to about  $\phi = 270^\circ$ . Before  $\phi \sim 90^\circ$  and after  $\phi \sim 270^\circ$ , the tip of the blade does not extend as far as the tip vortex left

by the preceding blade and no close interaction occurs. To clarify this, look at Fig. 5 and imagine another  $\eta$  blade at  $\psi = 60^\circ$  and  $\zeta = 180^\circ$ . This blade does not reach the tip vortex line.

A possible explanation for the observed reduction in airload peaks is the propagation of vortex bursting. When the rotor blade first starts sweeping over the tip vortex from the preceding blade, at about  $\phi = 90^\circ$ , normal bursting occurs. This means that the bursting occurs behind the blade, after the first close interaction. Thus, this first close interaction results in a large airload peak at about  $\phi = 90^\circ$ . This bursting instability then propagates up the tip vortex for increasing  $\phi$  at a rate faster than the rotor blade. Thus, the tip vortex can burst before the first close interaction for  $\phi > 90^\circ$ . This could explain the reduced airload peaks in this area.

This propagation of bursting is speculative. On the other hand, it is the only explanation which has been developed for the observed reduction in the airload peaks, due to the first close blade-vortex interaction, over the forward portion of the rotor disk. To investigate the propagation idea, a simple model has been developed. Propagation starts when the first close interaction occurs (normally near  $\phi = 90^\circ$ ). A uniform propagation rate and the  $\phi$  at which all propagation stops are input parameters which can be varied to test different theories.

To summarize, models have been developed for tip vortex-core bursting and the propagation of this bursting. The parameters defining these models are inputs which can be varied. Bursting is simulated by a simple increase in vortex-core radius, the vortex-core model remains unchanged. A segment of tip vortex which has already burst cannot be burst a second time by any subsequent close blade-vortex interactions.

### 2.5.2 Near Wake Caused by the Tip Vortex

Close blade-vortex interactions, which involve the concentrated tip vortex line, lead to extremely rapid spanwise variations of the bound circulation. This causes the shedding of some extra trailing wake which, in turn, modifies the bound circulation distribution by changing the induced angle-of-attack distribution. This extra trailing wake ultimately either rolls up with the tip vortex or becomes part of the distributed inboard trailing wake. The part of this wake just behind the blade which shed it (the near wake) has not had time to roll up and/or merge with the rest of the wake. This near wake, therefore, has an important effect on the airloads distribution, and hence the bound circulation distribution, which is not represented by the basic wake model. In addition to this near wake effect, Johnson [52] has shown that there are important lifting-surface effects on the airloads due to a close blade-vortex interaction.

The normal solution to this near wake problem is to use lifting-line theory with an  $n$  trailing vortex-line model. This solution is expensive and it neglects both lifting-surface effects and any rollup of the near wake. Furthermore, the  $n$  used is often too small to adequately represent the near wake due to a close blade-vortex interaction. For example, consider Fig. 10 which shows a distance of less than one chord between the positive and negative bound circulation peaks. Since the peaks are located randomly with respect to the  $n$  trailing vortex lines, these lines must be spaced no more than  $1/3$  chord apart to ensure hitting the peaks. This implies values of  $n$  around 50 for typical high aspect ratio rotor blades, which is very expensive.

A common solution to the rollup problem is to only use the  $n$  trailing vortex line model for the near wake, with a two trailing vortex line model (similar to the basic wake model) for the far wake. This is good as far as it goes, but it still requires the computation of induced velocities at  $(n-1)$  radial stations and

neglects lifting-surface effects. Lifting-surface theory could be applied to this model, but it would require the computation of induced velocities at several chordwise stations for each radial station. Taking a minimal 5 chordwise stations and  $(n-1) = 50$ , this implies the computation of induced velocities at 250 stations on the blade at each azimuth. This compares with the 6 stations normally used in this report.

To avoid this expense, superposition is used and the near wake due to each close blade-vortex interaction is treated separately. Johnson [52,53] has developed a planar lifting-surface solution for the loading on an infinite aspect ratio wing, due to an infinite, straight vortex line in a subsonic, compressible, free stream. The vortex line lies in a plane parallel to the plane of the wing, at a given distance below it and at an arbitrary angle with the wing centerline. Based on this solution, Johnson [52, 53] has developed an approximate analytical expression for the lift influence function. A simplified, incompressible version of this approximate expression is used for each individual close blade-vortex interaction. Since the tip vortex line is modelled by a series of straight-line segments, each of these segments is examined individually to see if it is involved in a close blade-vortex interaction.

The rotor blade has a finite aspect ratio, the vortex-line segment has a finite length, and the plane of the vortex line is not always parallel to the plane of the rotor blade, but all of these factors are neglected in applying this approximate lifting-surface solution. Furthermore, the lift-influence function is applied to the induced velocity contribution of the vortex-line segment instead of the lift. This implies that the lift-curve slope is constant. Notwithstanding all of these approximations this simplified lifting-surface solution is much more representative of near wake effects than a lifting-line solution. Furthermore, by applying this lifting-surface solution only at points

where it becomes important, a very efficient computation is achieved.

In summary, each tip vortex-line segment is examined to see if it is involved in a close blade-vortex interaction. If it is, then its contribution to the induced velocity at various points on the blade is multiplied by an approximate lift influence function developed by Johnson [52, 53]. Superposition is assumed to hold and the near wake due to anything but close blade-vortex interactions is neglected, except for a very approximate representation by the basic wake model and its extensions.

### 2.5.3 Tip Vortex Sheet Plus Vortex Line Model

In reality, the trailing wake is shed from the blade as a concentrated vortex line plus some distributed circulation. The concentrated vortex line is shed from the tip of the blade. The distributed circulation is shed inboard of the tip. Some of the distributed circulation eventually rolls up with the concentrated tip vortex. The rest of the distributed circulation remains spread out, at least near the rotor. In this work, the tip vortex is defined to include the concentrated tip vortex line, plus any distributed circulation which eventually rolls up with it. The rest of the distributed circulation is the inboard trailing wake.

In the basic wake model, it is assumed that, at each azimuth, all of the trailing wake shed outboard of the radial maximum in bound circulation will eventually roll up with the tip vortex (see Appendix D.4 for theoretical justification of this assumption). The normal basic wake model assumes that this rollup is instantaneous and that the concentrated tip vortex appears, full strength, at the tip of the blade. To test this assumption of instantaneous rollup, an alternative vortex sheet plus vortex line (VSVL) tip vortex model is used. This VSVL model represents both the concentrated and the distributed parts of the tip vortex, as well as the rollup process. The representation used is very simple, and not really suitable for a production program, but it is adequate to

evaluate the importance of rollup in airloads computations. The airloads program can use either the simple basic wake model (instantaneous rollup) or the VSVL tip vortex model. The wake geometry program uses only the simple instantaneous rollup model.

The tip vortex circulation, in the VSVL model, is initially split between a concentrated tip vortex line and a distributed tip vortex sheet. The concentrated tip vortex line is shed from the blade tip ( $\ell = 1.0$ ). The distributed vortex sheet is shed from a segment of the blade extending from the tip ( $\ell = 1.0$ ) inboard to a radial station  $\ell_t(\phi)$ . This  $\ell_t(\phi)$  is an input function of azimuth angle ( $\phi$ ) and is determined using the bound circulation distribution from a previous airloads computation for the same case.

The total circulation of the tip vortex line plus the tip vortex sheet is the same as the circulation of the tip vortex line in the simple instantaneous rollup model. The fraction of the total tip vortex circulation which is included in the concentrated tip vortex line at azimuth angle  $\phi$  and age  $\delta$  is  $f_t(\phi, \delta)$ . For the instantaneous rollup model  $f_t(\phi, \delta) = 1.0$  for all  $\phi$  and  $\delta$ .

For the VSVL Model:

$$f_t(\phi, \delta) = \text{Min.} \begin{cases} 1.0 \\ f_t^o(\phi) + \delta f_t^D \end{cases} \quad (2.8)$$

Thus,  $f_t(\phi, \delta)$  is assumed to be linear in age ( $\delta$ ) starting from an initial  $f_t^o(\phi) = f_t(\phi, 0)$  at the instant the wake element leaves the rotor blade ( $\delta = 0$ ). The function  $f_t^o(\phi)$  is an input to the program and, like  $\ell_t(\phi)$ , is determined using the bound circulation distribution from a previous airloads computation for the same case. The rollup rate ( $f_t^D$ ) is also an input to the program and is varied as a parameter.

The near wake segment of the tip vortex sheet is the segment just behind the  $\eta$  blade. This near wake must be handled with special care, due to its proximity to the points  $P_\eta$  on the  $\eta$  blade at which the induced velocity is being computed. To avoid the edge singularity, the radial station  $\ell_t(\phi)$  of the inner edge of the vortex sheet must always be chosen midway between adjacent points  $P_\eta$ . In addition, the geometry of the near tip vortex sheet must be very accurately defined relative to the  $\eta$  blade.

Normally, the geometry of a trailing vortex sheet segment is determined by translating a trailing vortex-line segment a distance  $\Delta x$  perpendicular to itself (see Appendix B). Since trailing vortex-line segments are not always perpendicular to the  $\ell$  blade which shed them, this can lead to either a gap or an overlap between the  $\ell$  blade and the vortex sheet (see Fig. 11). Ordinarily, this is not important, but for the near wake, the  $\ell$  blade is also the  $\eta$  blade, on which the induced velocity is being computed. So for the near wake case, no gap or overlap between the  $\eta$  blade and the vortex sheet can be allowed. The near wake vortex-sheet segment, therefore, extends back perpendicular to the  $\eta$  blade for a distance equal to the corresponding trailing vortex line (see Fig. 11).

The net result of the VSVL model is that the tip vortex sheet circulation decays linearly with time, while total tip vortex circulation remains constant. The dimensions of the tip vortex sheet do not change with time. A model where the vortex sheet rolls up into the vortex line like a window shade would be closer to what happens in reality. The VSVL model is much simpler to implement, however, and it is good enough to test the importance of modeling tip vortex rollup at all.

## 2.6 Inboard Trailing Wake

The inboard trailing wake is the wake caused by radial variations in bound circulation which is shed from that portion

of the rotor blade inboard of the peak bound circulation. It has a total circulation equal in magnitude but opposite in sign to that of the tip vortex. Unlike the tip vortex, the inboard trailing wake does not seem to roll up into a concentrated vortex line (at least not near enough to the rotor to affect the rotor airloads). This distributed nature of the inboard trailing wake means that its precise geometry is not as important as the geometry of the concentrated tip vortex line. This is fortunate because the computation of its geometry would involve the computation of the location of a network of points over a wide area. Compared to the computation of the location of points on a tip vortex line, this would be very expensive. For these reasons, only the simple "rigid wake" geometry is used for the inboard trailing wake in this report, with the exception of an empirical "prescribed" wake geometry used for some hovering cases.

Ideally, the inboard trailing wake should be represented by a vortex sheet of appropriately varying circulation. In practice, this vortex sheet is broken up into either vortex-line or vortex-sheet segments as described in Subsection 2.3. Azimuthally, these segments either have constant circulation or linearly varying circulation. Radial circulation variations could be represented by a multitude of vortex-line or vortex-sheet segments. As discussed in Subsection 2.2, this alternative is very expensive and is not used here. Instead, either a single vortex line or a single vortex sheet is used.

When the vortex-sheet model is used, the circulation of the vortex sheet does not vary with radius. This corresponds to a linear variation in bound circulation with radius. The inboard edge of the vortex sheet is normally taken to be at the blade root cutout radius. The outboard edge of the vortex sheet is an input function of azimuth angle  $\ell_1(\phi)$  for airloads computations, while it is computed in wake geometry computations. In either case, it is a function of the bound circulation distribution obtained from

a previous airloads computation, if available. This vortex-sheet model works well, but it is more expensive than the vortex-line model, due to the more complicated formula for the induced velocity contribution of a vortex-sheet segment.

The single vortex-line model is faster and simpler to use. However, it has the disadvantage of using a concentrated vortex line to represent a distributed vortex sheet. This can lead to close blade-vortex interactions which cause large airloads peaks. These peaks are products of the model and do not exist in reality where there is no concentrated vortex line to cause them. This problem can be alleviated by using a vortex line having a very large vortex-core radius. Normally, this vortex line is located radially in the middle of the average vortex sheet and has a vortex-core diameter equal to the width of this average vortex sheet. Basically, this corresponds to spreading out the vortex-line circulation over a circle whose diameter is equal to the width of the vortex sheet. Naturally, this three-dimensional spreading out of the circulation does not give the same answer as the two-dimensional spreading involved in a vortex sheet. However, the approximation is adequate for most purposes and this model is considerably less expensive than the vortex-sheet model. Since the vortex-core radius is artificial, there is no vortex core bursting.

The near portion of the inboard trailing wake (that part just behind the  $\eta$  blade) must be handled with some care. For the vortex-line model, it is necessary only to make sure that the center of the vortex line starts at a radial station midway between two adjacent points  $P_\eta$  at which airloads are computed. For the vortex-sheet model, the edges of the sheet must start at radial stations midway between two adjacent points  $P_\eta$ . In addition, the geometry of the vortex sheet must be very accurately defined relative to the  $\eta$  blade. This is covered in more detail for the near tip vortex sheet case in Subsection 2.5.3.

## 2.7 Shed Wake

The shed wake is all of the wake caused by azimuthal variations in the bound circulation. Like the inboard trailing wake, it is a distributed vortex sheet which does not appear to roll up near the rotor. Furthermore, the magnitude of the circulation in the shed wake is much less, sometimes as much as an order of magnitude less, than the trailing-wake circulation. Thus, the shed wake, with the exception of the near shed wake, can be treated fairly simply. The near shed wake must be handled carefully, due to the singularity as a shed vortex line approaches the points  $P_\eta$  on the  $\eta$  blade.

Normally, a vortex-line model is used for the shed wake with the exception of the near shed wake. This model consists of accumulating all of the change in bound circulation between azimuth angles  $\phi$  and  $\phi + \Delta\phi$  into a shed vortex line at azimuth angle  $\phi$ . The shed vortex line extends from a corner between two tip vortex-line segments to a corner between two inboard trailing vortex-line segments (see Fig. 7). To simulate the distributed nature of the shed wake an artificially large vortex-core radius, equal to half the distance between adjacent shed vortex lines, is used. A slightly more accurate model would place the shed vortex line at  $\phi + \Delta\phi/2$  instead of at  $\phi$ . However, this requires the use of vortex-line segment end points which are different from those used for the trailing wake. The increased accuracy is not worth the extra complication.

When a more accurate model is desired, the shed vortex-sheet model is used. This vortex sheet is generated by translating the shed vortex line forward, perpendicular to itself, from  $\phi$  to  $\phi + \Delta\phi$ . This model is considerably more expensive than the shed vortex-line model and is used only for exceptional cases.

The near shed wake is always modeled by a vortex sheet, due to its proximity to the points  $P_\eta$  on the  $\eta$  blade. If this near shed vortex-sheet segment were extended all of the way up to

the points  $P_\eta$ , there would be a singularity in the induced velocity at points  $P_\eta$ . Miller [9] presents a plot of  $\epsilon_s$  vs. reduced frequency ( $k = \frac{\omega b}{V}$ ), where  $\epsilon_s$  is the limit of the shed-wake integration for use in the lifting-line approximation. This plot was developed using classical two-dimensional unsteady aerodynamics. For typical helicopter reduced frequencies  $\epsilon_s$  is about 0.25 chord. Thus, the near shed wake vortex-sheet segment is generated by constructing a shed vortex-line segment  $\epsilon_s$  behind the points  $P_\eta$  on the  $\eta$  blade. This vortex-line segment is then translated backwards, perpendicular to itself, from  $\psi - \epsilon_s$  to  $\psi - \Delta\psi$  to generate the near vortex-sheet segment.

## 2.8 Determining the Circulation

The various vortex wake elements which make up the wake models have been described. Now the circulation of these wake elements must be determined. The circulation of the wake elements is determined, by conservation of circulation, from a bound circulation model. Circulation is conserved with two exceptions:

- 1) Wake elements which are very far away from point  $P_\eta$  are not included in the model and their contribution to the induced velocity at point  $P_\eta$  is neglected.
- 2) As an experiment, some cases were run where the inboard trailing wake was neglected: this approach was not a success.

The bound circulation model is normally based on the bound circulation distribution  $\gamma_\eta(\eta, \phi)$  obtained from a previous iteration of the airloads computation. For the zeroth iteration, no such bound circulation distribution is available and the bound circulation is assumed to have a constant average value  $\gamma_0$ , based on the thrust of the rotor. This means that there is no shed wake for this case and that all trailing wake elements have the same circulation.

The bound circulation  $\gamma_n(\eta, \phi)$  is computed at  $n_\eta$  (normally  $n_\eta = 6$ ) radial stations and  $n_\psi$  (normally  $n_\psi = 25$ ) azimuthal stations. For the basic wake model there is only one value of bound circulation  $\gamma_{bv}(\phi)$  at each azimuth. This saves computer time and core storage as discussed in Subsection 2.2. Thus, the radial bound-circulation distribution  $\gamma_n(\eta, \phi)$ , which is computed at  $n_\eta$  radial stations, must be modeled by a much simpler distribution which involves storing the value of only one bound circulation  $\gamma_{bv}(\phi)$  for each azimuth. There are different radial bound-circulation-distribution models, depending on the use of a vortex line or a vortex-sheet model of the inboard trailing wake and on the use of a tip vortex line only or a tip vortex sheet plus line model.

### 2.8.1 Vortex Line Trailing-Wake Models

For the simple basic wake model, where both the tip vortex and the inboard trailing wake are modeled by vortex lines, the radial bound-circulation model of Fig. 12 is used. The bound circulation  $\gamma_{bv}(\phi)$  is chosen to be the maximum bound circulation  $\gamma_n(\eta, \phi)$  at azimuth angle  $\phi$  for all  $\eta$  greater than  $\eta_{MEP}$  (normally  $\eta_{MEP} \simeq 0.5$ ). Since the radial stations  $\eta$  are spaced rather widely, a peak in  $\gamma_n(\eta, \phi)$  sometimes falls in between two adjacent radial stations  $\eta$ . In this case, interpolation is used to find  $\gamma_{bv}(\phi)$  based on  $\gamma_{bv}(\phi + \Delta\phi)$  and  $\gamma_{bv}(\phi - \Delta\phi)$ . The value of  $\ell_2$  is chosen to be midway between two adjacent points  $P_\eta$  and to be about midway between the root cutout ( $\ell_1$ ) of the blade and the average  $\ell_i(\phi)$  which would have been chosen if a vortex-sheet model had been used, see Subsection 2.6.

From Fig. 12, it is clear that the shed vortex-line circulation  $\gamma_s(\phi)$  is constant radially with this model. The azimuthal variation of  $\gamma_s(\phi)$  depends on  $\gamma_{bv}(\phi)$ :

$$\gamma_s(\phi) = \gamma_{br}(\phi + \Delta\phi) - \gamma_{br}(\phi) \quad (2.9)$$

If the shed vortex-line model is used, the trailing-wake circulation will be constant over each vortex-line segment and will vary between segments. For the tip vortex-line segment at azimuth angle  $\phi$ :

$$\gamma_a = \gamma_b = \gamma_{br}(\phi) \quad (2.10)$$

and for the inboard trailing vortex-line segment:

$$\gamma_a = \gamma_b = -\gamma_{br}(\phi) \quad (2.11)$$

If the shed vortex-sheet model is used, its circulation is constant both azimuthally and radially for each segment. This means that the trailing-wake circulation must vary linearly over each segment to conserve circulation. The values of  $\gamma_a$  remain as in Eqs. 2.10 and 2.11 and  $\gamma_b$  becomes:

$$\gamma_b = \gamma_{br}(\phi - \Delta\phi) \quad (2.12)$$

for the tip vortex-line segment and

$$\gamma_b = -\gamma_{br}(\phi - \Delta\phi) \quad (2.13)$$

for the inboard trailing vortex-line segment. The  $\gamma_a$  and  $\gamma_b$  used here are the circulations at the two ends of a vortex-line segment, see Appendix A.

### 2.8.2 Vortex-Sheet Trailing-Wake Models

For the modified basic wake model, where both the tip vortex and the inboard trailing wake are modeled by vortex sheets, the radial bound circulation model of Fig. 13 is used. As before, the bound circulation  $\gamma_{bv}(\phi)$  is the maximum  $\gamma_n(\eta, \phi)$  and interpolation is used as necessary. The values of  $\ell_i(\phi)$  and  $\ell_t(\phi)$  are chosen, outside of the computer, based on the  $\gamma_n(\eta, \phi)$  from a previous iteration. The value of  $\ell$  is normally the root cutout of the rotor blade.

From Fig. 13, it is clear that the shed-wake circulation  $\gamma_s(\phi)$  should be constant between  $\ell_i(\phi)$  and  $\ell_t(\phi)$  and should vary linearly between  $\ell_1$  and  $\ell_i(\phi)$  and between  $\ell_t(\phi)$  and the tip ( $\ell = 1.0$ ). This would require three shed-wake vortex-line segments at each azimuth angle  $\phi$ , which is expensive. The far-shed wake is not important enough to justify this expense. The normal solution is to use a single shed vortex-line (or sheet) segment which runs from  $\ell_2$  to the tip ( $\ell = 1.0$ ) and which has a constant circulation radially, given by Eq. 2.9. For some wake geometry computations, this constant circulation shed vortex line runs only from  $\ell_i(\phi)$  to the tip ( $\ell = 1.0$ ). There is then another shed vortex line running from  $\ell_1$  to  $\ell_i(\phi)$  which has a circulation varying linearly from 0.0 to  $\gamma_s(\phi)$ . This two-segment model is more expensive than the one segment model and is not used very often. The value of  $\ell_2$ , used in the one-segment model is normally midway between  $\ell_1$  and the average  $\ell_i(\phi)$ .

If the shed vortex-line model is used, the trailing-wake circulation will be constant over each trailing-wake segment and will vary between segments. For the tip vortex-line segment at azimuth angle  $\phi$ :

$$\gamma_a = \gamma_b = f_t(\phi, s) * \gamma_{bv}(\phi) \quad (2.14)$$

The total tip vortex-sheet-segment circulation will be:

$$\gamma_a = \gamma_b = [1.0 - f_t(\phi, s)] * \gamma_{bv}(\phi) \quad (2.15)$$

The total circulation of the inboard trailing-vortex-sheet segment is given by Eq. 2.11. Both of the vortex-sheet segments are of constant circulation radially and azimuthally.

If a shed vortex-sheet model is used, then the trailing-wake circulation must vary linearly over each segment to conserve circulation. This model is not normally used, but if necessary, the equations for  $\gamma_b$  can readily be derived from observation of the examples above.

It is possible to use the inboard trailing-vortex sheet with a tip vortex-line model or to use a tip vortex sheet plus vortex line model with an inboard trailing vortex line. For these cases, the radial bound circulation models of Figs. 12 and 13 can be mixed as necessary. The circulation can be computed using appropriate selections from Eqs. 2.10 through 2.15.

It should be observed that all of the circulation models given in this section depend on only one  $\gamma_{bv}(\phi)$  at each azimuth. This saves computer time and core storage as discussed in Subsection 2.2. It might be desirable to change the  $\ell_i(\phi)$  and  $\ell_t(\phi)$  in the computer during the circulation iteration, since these variables are functions of  $\gamma_n(\eta, \phi)$ . This amounts to changing the wake geometry and as discussed in Subsection 2.2, this would make circulation iterations much more expensive. On these grounds, it is suggested that  $\ell_i(\phi)$  and  $\ell_t(\phi)$  should be allowed to change much less often than every circulation iteration. In the current program, they are only changed externally between computer runs.

### SECTION 3

#### ROTOR HARMONIC AIRLOADS COMPUTATION

A rotor harmonic airloads computation scheme, and a computer program (LDS-73) which uses that scheme have been developed. The airloads computation has two functions. It provides the angle of attack  $\alpha(\eta, \psi)$  which the wake geometry computation (WG-71) uses to compute bound circulation  $\gamma_n(\eta, \psi)$ , and it is used to evaluate the influence of tip-vortex distortion on rotor harmonic-airloads computations. The airloads computation is not concerned with rotor blade structural response to the harmonic airloads, except where the response is large enough to change the airloads. The airloads computation is primarily intended for use at low advance ratios where the influence of tip-vortex distortion on harmonic airloads is expected to be most important. For these reasons, the blade-dynamics modeling and dynamic-stall modeling is relatively simple, while the aerodynamic modeling is sophisticated. It is anticipated that an industrial user of this work would use the aerodynamic models, but would provide his own blade-dynamics and blade-section aerodynamics to whatever level of sophistication is necessary.

The airloads program LDS-73 computes the rotor airloads for a given wake geometry. If the effects of tip-vortex distortion are to be included in the computation, then LDS-73 is used together with WG-71. This program computes the tip-vortex distortion  $\hat{D}(\psi, \delta)$  for a given bound circulation distribution  $\gamma_n(\eta, \psi)$ . The relationship between LDS-73 and WG-71 is shown in Fig. 3.

The basic inputs to LDS-73 are a physical description of the rotor, the operating condition of the rotor, the initial bound circulation distribution (which can be simply a constant,  $\gamma_0$ ), and a group of parameters indicating which wake model and which of the many different computation options are to be used. In addition, the tip-vortex distortion  $\hat{D}(\psi, \delta)$  and a set of experimental airloads

XLDS( $\eta, \psi$ ) can be introduced as input, if necessary. The outputs are the airloads distribution  $L(\eta, \psi)$ , various overall performance parameters (such as rotor  $L/D_E$ ), rotor blade motion, the rotor downwash distribution  $\lambda(\eta, \psi)$ , the rotor angle-of-attack distribution  $\alpha(\eta, \psi)$ , the bound circulation distribution  $\gamma_n(\eta, \psi)$ , and a mass of detailed data which supports these results. For a detailed account of these inputs and outputs, see Appendix E.

During the evaluation of the effects of tip-vortex distortion on rotor harmonic airloads, the vital importance of close blade-vortex interactions became evident. A substantial program of fundamental research will be required to fully understand this problem. To help guide such research, an evaluation has been made here of the effect on rotor harmonic airloads of various close blade-vortex interaction phenomena. These phenomena include the tip-vortex core, tip vortex-core bursting, the propagation of tip-vortex-core bursting, lifting-surface effects, near wake effects, and local stall due to large radial pressure gradients. Most of these phenomena are modeled very simply, which is appropriate for our current level of understanding. Further investigation may show that some of these phenomena do not exist in the form postulated here, or it may show that other phenomena, not considered here, are important. It is clear, however, that some sort of close blade-vortex interaction phenomena exist which have an important effect on rotor-blade harmonic airloads, especially when tip-vortex distortion is included.

### 3.1 Bound-Circulation Computation

#### 3.1.1 Bound-Circulation Iteration

A simplified flow chart for LDS-73 is given in Fig. 14. This flow chart emphasizes the basic bound circulation iteration. The program starts by reading input data and initializing various constants. Then the bound-circulation distribution for the  $n$ th iteration  $\gamma_n(\eta, \psi)$  is computed. There are two basic options here,

depending on whether or not an angle-of-attack distribution  $\alpha(\eta, \psi)$  is available from a previous run of LDS-73. If it is not available, then this is a zeroth iteration and  $\gamma_0(\eta, \psi)$  is equal to a constant  $\gamma_0$ , which is an input. If  $\alpha(\eta, \psi)$  is available, then this is a first iteration and  $\gamma_1(\eta, \psi)$  is computed from  $\alpha(\eta, \psi)$ :

$$\gamma_1(\eta, \psi) = \frac{a}{2\pi} (\eta + \mu \sin \psi) \alpha(\eta, \psi) \quad (3.1)$$

where  $a = \frac{\partial C_L}{\partial \alpha}$  is the lift-curve slope, and  $\mu = \frac{V}{\Omega R}$  is the advance ratio.

The basic wake model bound circulation  $\gamma_{bv}(\phi)$  is computed from  $\gamma_n(\eta, \psi)$ . For a zeroth iteration,  $\gamma_{bv}(\phi)$  is simply equal to  $\gamma_0$ . Otherwise,  $\gamma_{bv}(\phi)$  is the radial peak  $\gamma_n(\eta, \psi)$ , with interpolation used as necessary, see Subsection 2.8. This  $\gamma_{bv}(\phi)$  is used to compute the downwash distribution  $\lambda(\eta, \phi)$ . Subroutine LOADS uses  $\lambda(\eta, \psi)$  to compute blade motion and airloads. One result of this airloads computation is a new angle-of-attack distribution  $\alpha(\eta, \psi)$ . This ends an iteration.

To start a new iteration,  $\alpha(\eta, \psi)$  is used to compute  $\gamma_{n+1}(\eta, \psi)$ . If this is the first iteration, i.e., there is no old  $\gamma_n(\eta, \psi)$ , except  $\gamma_0(\eta, \psi) = \gamma_0$ , then Eq. 3.1 is used. Otherwise, a weighted average of the  $\gamma(\eta, \psi)$  obtained from the new  $\alpha(\eta, \psi)$  and the old  $\gamma_n(\eta, \psi)$  is used:

$$\gamma_{n+1}(\eta, \psi) = w_f \left( \frac{a}{2\pi} (\eta + \mu \sin \psi) \alpha(\eta, \psi) \right) + (1 - w_f) \gamma_n(\eta, \psi) \quad (3.2)$$

where  $w_f$  is an input; normally  $w_f = 0.5$ . The iteration then proceeds as described above. After the last iteration is completed and a final  $\alpha(\eta, \psi)$  is obtained, there is a final  $\gamma_{n+1}(\eta, \psi)$  computation using Eq. 3.2. This  $\gamma_{n+1}(\eta, \psi)$  and the corresponding  $\gamma_{bv}(\phi)$  is printed and plotted by LDS-73 for comparison with  $\gamma_n(\eta, \psi)$  to determine convergence.

There is no test for bound circulation convergence in the program LDS-73. The number of iterations to be done is an input.

Normally, five iterations are sufficient. If QMAT is not recomputed, and if most of the output for the intermediate iterations is suppressed (see Appendix E), then extra iterations are not expensive. The normal test for convergence is the output comparison plot of the last and next to the last  $\gamma_{bv}(\phi)/\gamma_o$  (see Appendix E).

### 3.1.2 Bound-Circulation Models

The bound circulation models are covered in Subsection 2.8. The far-shed vortex sheet model of Subsection 2.8 is not used in LDS-73. This is because runs were made using this model which showed no advantage over the simpler shed-vortex-line model.

One point which may cause confusion is the use of  $\gamma_n(\eta, \phi)$  in Subsection 2.8 vs.  $\gamma_n(\eta, \psi)$  in Subsection 3.1. Also  $\gamma_{bv}(\phi)$  is obtained from  $\gamma_n(\eta, \psi)$  in Subsection 3.1. The problem is that  $\gamma_n(\eta, \psi)$  is computed at points  $P_n$ , which are at azimuth angle  $\psi$ . Then  $\gamma_n(\eta, \phi)$  or  $\gamma_{bv}(\phi)$  are used to define the circulation of a wake element at azimuth angle  $\phi$ . Thus the function  $\gamma_n$  remains the same, only the azimuth angle at which  $\gamma_n$  is evaluated changes. This same situation will occur in WG-71 when the distortion  $\vec{D}$  is computed:  $\vec{D}(\psi, \delta)$ , or is used:  $\vec{D}(\phi, \delta)$ . In LDS-73, the distortion is read in as  $\vec{D}(\psi, \delta)$  and is used as  $\vec{D}(\phi, \delta)$ .

### 3.2 Induced-Velocity Computation

The computation of the induced velocity at points  $P_n$  on the rotor is the heart of the airloads computation. The induced contribution to the downwash  $\lambda(\eta, \psi)$  is the source of high harmonic airloads. The ability to predict these high harmonic airloads is the chief object of this work. Also, the induced velocity computation is the most time-consuming part of the airloads computation. For a typical four-bladed rotor case run on LDS-73, the induced velocity computation takes about 30 seconds compared to less than one second for the rest of a circulation iteration. Subsequent iterations take less than one second each, unless QMAT is recomputed (see Subsection 3.2.2).

The induced velocity influence coefficient matrix QMAT is a function of the wake model and the wake geometry relative to points  $P_n$  on the rotor. If QMAT is to be held constant during a complete airloads computation, then these items must also be constant. The distortion  $\hat{D}$  is constant during an airloads computation by LDS-73, because  $\hat{D}$  is only computed by WG-71, a separate program. However, blade motion could still change the location of point  $P_n$  relative to the wake. The effect of zeroth harmonic flapping  $a_0$  is included by input of a constant value of  $a_0$  based on the thrust coefficient  $C_T$ :

$$a_0 = \frac{3}{4} \left( \frac{LN}{2\pi} \right) \left( \frac{C_T}{\sigma} \right) \quad (3.3)$$

where  $\sigma$  = rotor solidity and  $LN$  = Lock Number =  $\frac{2\pi\rho c R^4}{T_b}$ . This is normally adequate. A more complicated expression with twist and downwash effects is given in Eq. 3.124. The effect of first harmonic flapping is included by computing the wake geometry relative to the tip path plane (TPP) and using a constant  $i$ , where  $i$  is the incidence of the TPP to the relative wind (Fig. 15). At low advance ratios, the thrust  $T$  is very nearly perpendicular to the TPP ( $C_H$ , the horizontal force coefficient, is computed by LDS-73 to check on this). Thus,  $i$  is easily calculated, if the rotor propulsive force  $X$  is known:

$$i = \sin^{-1} (X/T) \quad (3.4)$$

The effect of higher harmonics of flapping and of all other blade motion on wake geometry is neglected.

The requirement that the wake model remain constant has a more serious effect on the airloads computation. It means that the parameters  $l_i(\phi)$ ,  $l_t(\phi)$ ,  $f_t^O(\phi)$ , and  $f_t^D$ , which define the in-board trailing and tip vortex sheets (Subsections 2.5 and 2.6), cannot be changed during an airloads computation, unless QMAT is recomputed. In LDS-73, these parameters are inputs which remain constant during a run. However, they are a function of the bound

circulation distribution  $\gamma_n(\eta, \psi)$ . In a program more advanced than LDS-73, it might be desirable to compute these parameters internally as part of the  $\gamma_n(\eta, \psi)$  iteration. This will require either abandoning QMAT or greatly expanding it to include several different radial stations. This will require a lot of core storage and may not be worth the cost.

### 3.2.1 Induced Velocity Influence Coefficient Matrix QMAT

To save computation time, the induced part of  $\lambda(\eta, \psi)$  is split into two pieces. One is an influence coefficient matrix QMAT, which only depends on the geometry of the wake relative to the points  $P_n$  on the rotor, and on the wake model. The other is the wake circulation distribution which only depends on the bound circulation  $\gamma_{bv}(\phi)$ . If the wake geometry and the wake model are not changed during a complete airloads computation, then QMAT only needs to be computed once for the initial iteration. Since the computation of QMAT is typically 30 times as long as the rest of an iteration, this is an important saving.

QMAT is a large matrix and it is important to minimize the size of QMAT to save computer core storage. This QMAT storage problem is one of the reasons for the choice of the basic wake model over the  $n$  trailing vortex-line model, Subsection 2.2. To minimize the size of QMAT, consider its components. First, QMAT is a function of the location of point  $P_n$ , where the induced velocity is computed. This location is specified by  $\eta$  and  $\psi$ , see Subsection 1.5. Normally, there are six radial stations  $\eta$  and twenty-five azimuth stations  $\psi$ .

QMAT is also a function of the circulation distribution in the wake. However, in the basic wake model, the circulation of each wake element is completely determined by the bound circulation  $\gamma_{bv}(\phi)$  for a fixed wake model. There are normally at least three wake elements per rotor blade for each  $\gamma_{bv}(\phi)$ : tip vortex, inboard

trailing wake, and shed wake. Also  $\gamma_{bv}(\phi)$  is cyclic every  $2\pi$  in  $\phi$ , due to the assumption of steady-state flight, Subsection 1.4. Thus, QMAT storage is minimized by summing QMAT over the various rotor blades ( $\zeta$ ), the various wake spirals ( $2\pi$  in azimuth), and the different wake elements ( $l$ ). In this context  $l_1$  refers to the shed wake,  $l_2$  refers to the inboard trailing wake, and  $l_3$  refers to the tip vortex. This leaves QMAT a function of  $\eta$ ,  $\psi$ , and  $\phi$ , where  $\phi$  is cyclic over every  $2\pi$  interval. Typically, there are twenty-five azimuth stations  $\phi$ ; thus, QMAT requires  $6\eta * 25\psi * 25\phi = 3750$  words of storage (about 15k bytes).

Now  $QMAT(\eta, \psi, \phi)$  can be defined such that the distribution of downwash perpendicular to the TPP is:

$$\lambda(\eta, \psi) = \mu \tan i + \left(\frac{b}{2R}\right) \sum_{\phi} \left[ \gamma_{bv}(\phi) * QMAT(\eta, \psi, \phi) \right] \quad (3.5)$$

The  $\mu \tan i$  term is the component of the relative wind perpendicular to the TPP. The factor  $b/2R$  appears because QMAT is normalized by  $\Gamma/4\pi R$ , while  $\gamma_{bv}(\phi)$  is given by  $\Gamma/2\pi b\Omega R$  and  $\lambda(\eta, \psi)$  is normalized by  $\Omega R$ . This normalization of QMAT is chosen to avoid multiplying each individual entry in the QMAT matrix by  $b/2R$ . In LDS-73, the  $\gamma_{bv}(\phi)$  are all multiplied by  $b/2R$  as they are computed. This minimizes the number of multiplications.

Define  $q_k(\eta, \psi, \zeta, l, \phi)$  as the contribution of the wake element identified by  $\zeta, l$ , and  $\phi$  (see Subsection 1.5) to the induced velocity component perpendicular to the TPP at point  $P_\eta$ . Let  $q_k(\eta, \psi, \zeta, l, \phi)$  be normalized by  $\Gamma/4\pi R$ , where  $\Gamma$  is the circulation of the wake element ( $ft^2/sec$ ). Now  $QMAT(\eta, \psi, \phi)$  can be computed:

$$QMAT(\eta, \psi, \phi) = \sum_{\zeta} \sum_{n=0}^{m-1} \left[ \sum_{l=l_2}^{l_3} q_k(\eta, \psi, \zeta, l, \phi + 2\pi n) + q_k(\eta, \psi, \zeta, l_1, \phi - \Delta\phi + 2\pi n) - q_k(\eta, \psi, \zeta, l_1, \phi + 2\pi n) \right] \quad (3.6)$$

The two  $\lambda_1$  terms arise because the shed wake element circulation is:

$$\gamma_s(\phi) = \gamma_{bv}(\phi + \Delta\phi) - \gamma_{bv}(\phi) \quad (2.9)$$

The summation over  $n$  is due to the cyclic nature of  $\gamma_{bv}(\phi)$  and hence of QMAT  $(\eta, \psi, \phi)$ . The upper limit  $m$  is the number of spirals (revolutions) of wake included in the wake model.

### 3.2.2 Induced Velocity SUM Matrix

The SUM matrix is the matrix of  $q_z(\eta, \psi, \zeta, \ell)$ , which is called SUM in LDS-73. This  $q_z(\eta, \psi, \zeta, \ell)$  is the contribution of all of the wake associated with a particular rotor blade ( $\zeta$ ), and type of wake ( $\ell$ ): shed wake, inboard trailing wake, or tip vortex, to  $\lambda(\eta, \psi)$ . It is computed by summing the contributions of the various wake elements over  $\phi$ :

$$q_z(\eta, \psi, \zeta, \ell) = \left(\frac{b}{2R}\right) \sum_{\delta=0}^{2\pi m} \gamma_a \times q'_k(\eta, \psi, \zeta, \ell, \delta) \quad (3.7)$$

where  $\gamma_a$  is the wake element circulation (see Subsection 2.8). The function  $q'_k(\eta, \psi, \zeta, \ell, \delta)$  is the same as  $q_k(\eta, \psi, \zeta, \ell, \phi)$ , except that the age of point  $P_\delta(\delta)$  has replaced  $\phi$ . Recall from Subsection 1.5

$$\delta = \psi + \zeta - \phi \quad (1.3)$$

This SUM matrix can now be used to compute  $\lambda(\eta, \psi)$ :

$$\lambda(\eta, \psi) = \mu \tan i + \sum_{\zeta} \sum_{\ell} q_z(\eta, \psi, \zeta, \ell) \quad (3.8)$$

This computation of  $\lambda(\eta, \psi)$  is done as a check on the results of Eq. 3.5 whenever  $q_z(\eta, \psi, \zeta, \ell)$  is available. Since QMAT  $(\eta, \psi, \phi)$  has already been summed over  $\zeta$  and  $\ell$ ,  $q_z(\eta, \psi, \zeta, \ell)$  cannot be obtained from QMAT  $(\eta, \psi, \phi)$ . Thus,  $q_z(\eta, \psi, \zeta, \ell)$  is only available for those circulation iterations where subroutine QLDS is called to compute a new QMAT and  $q_z(\eta, \psi, \zeta, \ell)$ .

The primary reason for computing and storing the SUM matrix

$q_z(\eta, \psi, \zeta, \ell)$  is to permit its print-out. This allows the user to determine the contribution of each individual rotor blade ( $\zeta$ ) and each type of wake ( $\ell$ ) to  $\lambda(\eta, \psi)$ . This is often very useful information and it is sometimes worth the extra expense to have QMAT recomputed on the last circulation iteration of a LDS-73 run, just to obtain  $q_z(\eta, \psi, \zeta, \ell)$  for the final, converged  $\gamma_{bv}(\phi)$ .

The SUM matrix is quite large (typically  $6\eta * 25\psi * 6\zeta * 3\ell = 2700$  words). Unlike QMAT, the SUM matrix is of no use once it has been printed out and  $\lambda(\eta, \psi)$  has been computed. Thus, all of the large variable arrays associated with the blade motion and airloads computations can be stored in the same space as SUM. This greatly reduces the storage penalty associated with SUM.

### 3.2.3 Tip Vortex

Define an  $x, y, z$  coordinate system with origin at point  $P_\eta$ , where the induced velocity is to be computed. A set of unit vectors is defined  $\hat{i}, \hat{j}, \hat{k}$  corresponding to  $x, y, z$ , respectively. The  $y$  axis and  $\hat{j}$  are parallel to the tip path plane (TPP) and are directed downstream (Fig. 16). The  $x$ -axis and  $\hat{i}$  are parallel to the TPP and are directed to starboard. The  $z$ -axis and  $\hat{k}$  are perpendicular to the TPP and are directed downward, making a right-handed, rectangular coordinate system.

The various tip vortex models are described in Subsection 2.5. All of these models start from a tip vortex line made up of straight-line segments. The geometry of such a line segment is defined by the vectors  $\vec{a}$  and  $\vec{b}$  from point  $P_\eta$  to the ends of the segment (Fig. 16). The components of these vectors are:

$$\vec{a} = x_a \hat{i} + y_a \hat{j} + z_a \hat{k} \quad (3.9)$$

$$\vec{b} = x_b \hat{i} + y_b \hat{j} + z_b \hat{k} \quad (3.10)$$

To compute these components, recall that the advance ratio  $\mu$  and the mean inflow  $\lambda$  are both normalized by rotor tip speed  $\Omega R$  and that azimuth angles are measured in radians. Thus, the rotor

hub will move upstream a distance  $\mu\delta$  as the rotor rotates through azimuth angle  $\delta$ . A review of the notation defined in Subsection 1.5 is suggested.

For the rigid-wake case, the horizontal components are readily found using Fig. 16:

$$x_a = l \sin \phi - \eta \sin \psi \quad (3.11)$$

$$x_b = l \sin(\phi - \Delta\phi) - \eta \sin \psi \quad (3.12)$$

$$y_a = l \cos \phi - \eta \cos \psi + \mu \delta \quad (3.13)$$

$$y_b = l \cos(\phi - \Delta\phi) - \eta \cos \psi + \mu(\delta + \Delta\phi) \quad (3.14)$$

where the age  $\delta$  of point  $P_\ell$  is:

$$\delta = \psi + \zeta - \phi \quad (1.3)$$

and  $l = l_3$  for the tip vortex.

For the rigid-wake case, the wake moves downwards perpendicular to the TPP by  $\lambda\delta$  as the rotor rotates through an angle  $\delta$ , where  $\lambda$  is a mean inflow input to LDS-73 just for this purpose. Including the effect of zeroth harmonic flapping  $a_0$ , the vertical components are (for rigid wake):

$$z_a = \lambda\delta - a_0(l - \eta) \quad (3.15)$$

$$z_b = \lambda(\delta + \Delta\phi) - a_0(l - \eta) \quad (3.16)$$

where  $a_0$  is another input to LDS-73 and can be estimated using Eq. 3.3.

For the distorted wake case, the distortion  $\vec{D}(\phi, \delta)$  must be included. The distortion is computed by WG-71 and input to LDS-73.

It has components:

$$\vec{D}(\phi, \delta) = D_1(\phi, \delta) \vec{i} + D_2(\phi, \delta) \vec{j} + D_3(\phi, \delta) \vec{k} \quad (3.17)$$

The horizontal components of  $\vec{a}$  and  $\vec{b}$  become (for distorted wake):

$$x_a = l \sin \phi - \eta \sin \psi + D_1(\phi, \delta) \quad (3.18)$$

$$x_b = l \sin(\phi - \Delta\phi) - \eta \sin \psi + D_1(\phi - \Delta\phi, \delta + \Delta\phi) \quad (3.19)$$

$$y_a = l \cos \phi - \eta \cos \psi + \mu \delta + D_2(\phi, \delta) \quad (3.20)$$

$$y_b = l \cos(\phi - \Delta\phi) - \eta \cos \psi + \mu(\delta + \Delta\phi) + D_2(\phi - \Delta\phi, \delta + \Delta\phi) \quad (3.21)$$

For the vertical components of  $\vec{a}$  and  $\vec{b}$ , recall that  $\vec{D}(\phi, \delta)$  includes the effect of the induced part of  $\lambda$  but not the effect of the component of the relative wind perpendicular to the TPP ( $\mu \tan i$ ):

$$z_a = \delta \mu \tan i - a_o(l - \eta) + D_3(\phi, \delta) \quad (3.22)$$

$$z_b = (\delta + \Delta\phi) \mu \tan i - a_o(l - \eta) + D_3(\phi - \Delta\phi, \delta + \Delta\phi) \quad (3.23)$$

where  $i$  is the angle between the TPP and the relative wind (Fig. 15) and is an input to LDS-73 (Eq. 3.4).

The circulation of the vortex-line segment must be known in addition to  $\vec{a}$  and  $\vec{b}$ . The wake models of LDS-73 all use constant circulation trailing-wake segments. Thus, only  $\gamma_a$ , the normalized circulation at point  $P_a$ , is required. When the tip vortex is modeled by only a vortex line, then

$$\gamma_a = \gamma_{br}(\phi) \quad (2.10)$$

When the tip vortex sheet plus vortex-line model is used (Subsection 2.5.3),

$$\gamma_a = f_t(\phi, \delta) * \gamma_{bv}(\phi) \quad (2.14)$$

For the computation of  $\gamma_{bv}(\phi)$ , see Subsection 3.1.

The contribution of a straight vortex-line segment to the induced velocity at point  $P_\eta$  is derived in Appendix A as:

$$\vec{q}_{VL} = \gamma_a \left( \frac{b}{2R} \right) \left[ \frac{(|\vec{a}| + |\vec{b}|)(|\vec{a}||\vec{b}| - \vec{a} \cdot \vec{b})}{|\vec{a}||\vec{b}| |\vec{a} \times \vec{b}|^2} \right] (\vec{a} \times \vec{b}) \quad (A.24)$$

This  $q_{VL}$  is normalized by tip speed and is parallel to  $\vec{a} \times \vec{b}$ . It also neglects all vortex core and close blade-vortex interaction effects. Define the components of  $\vec{a} \times \vec{b}$  as:

$$\vec{a} \times \vec{b} = (a \times b)_i \vec{i} + (a \times b)_j \vec{j} + (a \times b)_k \vec{k} \quad (3.24)$$

Define  $F_c$  as a correction factor which multiplies  $\gamma_a$  to correct for all vortex core and close blade-vortex interaction effects. Recall that QMAT is multiplied by  $(b/2R)\gamma_{bv}(\phi)$  to get  $\lambda(\eta, \psi)$ ; hence the  $f_t(\phi, \delta)$  factor in  $\gamma_a$  must be included in QMAT. For the instantaneous tip vortex rollup case, where Eq. 2.10 is used for  $\gamma_a$ , the factor  $f_t(\phi, \delta)$  is always equal to one. From Eq. 3.6, QMAT is a sum of  $q_k(\eta, \psi, \zeta, \ell, \phi)$ . From Subsection 3.2.1,  $q_k(\eta, \psi, \zeta, \ell, \phi)$  is normalized by  $\Gamma/4\pi R$  instead of  $\Omega R$ . From the definition of  $\gamma_a$ ,

$$\frac{\Gamma}{4\pi R} = \gamma_a \left( \frac{b}{2R} \right) \Omega R \quad (3.25)$$

Therefore, the tip vortex-line segment contribution is

$$q_k(\eta, \psi, \zeta, \ell, \phi) = F_c * f_t(\phi, \delta) \left[ \frac{(|\vec{a}| + |\vec{b}|)(|\vec{a}||\vec{b}| - \vec{a} \cdot \vec{b})}{|\vec{a}||\vec{b}| |\vec{a} \times \vec{b}|^2} \right] (a \times b)_k \quad (3.26)$$

Similar expressions can be written for the induced velocity components in the  $\vec{i}$  and  $\vec{j}$  directions. The calculation of  $F_c$  will be described in Subsection 3.2.4.

If the tip vortex sheet plus vortex line model is used, the contribution of the vortex-sheet segment must be added to the results of Eq. 3.26. Except for the near wake case, the geometry of the tip-vortex sheet is determined by translating the tip vortex line inboard, perpendicular to itself, from  $\ell = 1.0$  to  $\ell = \ell_t(\phi)$ . The geometry is specified by four parameters  $\vec{a}$ ,  $\vec{b}$ ,  $\Delta\tilde{x}$ , and  $z_m$ . The  $\vec{a}$  and  $\vec{b}$  are the same as in the tip vortex-line case, see above. The length of the vortex sheet is:

$$\Delta\tilde{x} = 1.0 - \ell_t(\phi) \quad (3.27)$$

The  $z$  component of a vector from point  $P_\eta$  to the midpoint of the  $\ell_t(\phi)$  edge of the vortex sheet is:

$$z_m = 0.5 (z_a + z_b) - a_0 \Delta\tilde{x} \quad (3.28)$$

where  $z_a$  and  $z_b$  are the  $z$  components of  $\vec{a}$  and  $\vec{b}$  (Eqs. 3.15 and 3.16 or 3.22 and 3.23) and  $a_0$  is the zeroth harmonic of rigid body flapping.

The computation of the contribution of a vortex sheet segment to the induced velocity at point  $P_\eta$  is complex. The numerous equations required are developed in Appendix B. The ultimate result ( $\vec{q}_{vs}$ ) is normalized by  $\Omega R$ . To get the contribution to  $q_k(\eta, \psi, \zeta, \ell_3, \phi)$ , take the  $\vec{k}$  component of  $\vec{q}_{vs}$ , eliminate the  $\gamma_a(b/2R)$  factor in front, and multiply by  $[1 - f_t(\phi, \delta)]$ . For example, if the  $\vec{q}_{vs}$  of Eq. B.69 is used (the constant circulation, no vortex-core case), then

$$\Delta q_k(\eta, \psi, \zeta, \ell_3, \phi) = [1 - f_t(\phi, \delta)] (\mathcal{I}_1 z_x + \mathcal{I}_2 z_z) \quad (3.29)$$

The analogous expression including the vortex core is

$$\Delta q_k(\eta, \psi, \zeta, \ell_3, \phi) = [1 - f_t(\phi, \delta)] \left[ (\mathcal{I}_{1a} + \mathcal{I}_{1b}) z_x + (\mathcal{I}_{2a} + \mathcal{I}_{2b}) z_z \right] \quad (3.30)$$

For the near-wake case, a special tip vortex-sheet geometry must be used (Subsection 2.5.3). The vortex-sheet segment is taken perpendicular to the rotor blade instead of to the tip vortex line. In the notation of Appendix B:

$$C_a = 0 \quad (3.31)$$

$$C_b = \Delta\phi \quad (3.32)$$

$$x_1 = 1.0 - \eta \quad (3.33)$$

$$x_2 = l_t(\phi) - \eta \quad (3.34)$$

$$z_\perp = 0 \quad (3.35)$$

and  $\Delta\tilde{x}$  is given by Eq. 3.27. When  $l_t(\phi) \leq \eta \leq 1.0$ , there is a singularity, but it is integrable as long as  $\eta$  is not allowed to equal either 1.0 or  $l_t(\phi)$ . Due to  $C_a$  and  $z$  being equal to zero, the computations are greatly simplified and the results are given here. For the case of no vortex core ( $\rho_{vs} = 0$ ):

$$\Delta q_k(\eta, \psi, \zeta, l_3, \phi) = [1 - f_t(\phi, \zeta)] \ln \left| \frac{x_2(\sqrt{C_b^2 + x_1^2} - C_b)}{x_1(\sqrt{C_b^2 + x_2^2} - C_b)} \right| \frac{1}{\Delta\tilde{x}} \quad (3.36)$$

When  $C_b < \rho_{vs}$ :

$$\Delta q_k(\eta, \psi, \zeta, l_3, \phi) = \frac{C_b[1 - f_t(\phi, \zeta)]}{\Delta\tilde{x}\sqrt{\rho_{vs}^2 - C_b^2}} \left[ \tan^{-1} \left( \frac{\sqrt{C_b^2 + x_1^2}}{\sqrt{\rho_{vs}^2 - C_b^2}} \right) - \tan^{-1} \left( \frac{\sqrt{C_b^2 + x_2^2}}{\sqrt{\rho_{vs}^2 - C_b^2}} \right) \right] \quad (3.37)$$

When  $C_b > \rho_{vs}$ :

$$\Delta q_k(\eta, \psi, \zeta, l_3, \phi) = \frac{C_b [1 - f_t(\phi, \zeta)]}{2\Delta \tilde{x} \sqrt{C_b^2 - \rho_{vs}^2}} \ln \left[ \frac{(\sqrt{C_b^2 + x_1^2} - \sqrt{C_b^2 - \rho_{vs}^2})(\sqrt{C_b^2 + x_2^2} + \sqrt{C_b^2 - \rho_{vs}^2})}{(\sqrt{C_b^2 + x_1^2} + \sqrt{C_b^2 - \rho_{vs}^2})(\sqrt{C_b^2 + x_2^2} - \sqrt{C_b^2 - \rho_{vs}^2})} \right] \quad (3.38)$$

### 3.2.4 Tip Vortex Core and Close Blade-Vortex Interaction Effects

The tip vortex correction factor  $F_c$  is used to include all vortex core and close blade-vortex interaction effects on the induced velocity  $q_k(\eta, \psi, \zeta, l, \phi)$ . The correction factor  $F_c$  is the product of the vortex core factor  $\gamma_c(\rho)$  and the close blade-vortex interaction factor  $q_f$ :

$$F_c = q_f * \gamma_c(\rho) \quad (3.39)$$

The vortex core factor  $\gamma_c(\rho)$  is the fraction of the total tip vortex-line segment circulation  $\gamma_a$  which is within a distance  $\rho$  of the center of the vortex line. For large  $\rho$  this fraction  $\gamma_c(\rho)$  goes to 1.0 and can be neglected. The function  $\gamma_c(\rho)$  depends on the choice of vortex-core model (Subsection 2.4). The normal choice is the fixed-wing vortex-core model, for which:

$$\gamma_c(\rho) = \frac{\rho^2}{1 + \rho^2} \quad (2.3)$$

The distance  $\rho$  is normalized by the vortex-core radius  $\rho_c$ . The length of a perpendicular dropped from point  $P_\eta$  to the vortex-line segment (or its extension) is  $h$  (normalized by  $R$ ). From Eqs. A.19 and A.20 in Appendix A:

$$h = \frac{|\vec{a} \times \vec{b}|}{|\vec{z}|} \quad (3.40)$$

Recalling that  $\rho_c$  is normalized by  $R$ :

$$\rho = h / \rho_c = \frac{|\vec{a} \times \vec{b}|}{|\vec{z}| \rho_c} \quad (3.41)$$

For the fixed-wing vortex-core model:

$$\gamma_c(\rho) = \frac{h^2}{h^2 + \rho_c^2} = \frac{|\vec{a} \times \vec{b}|^2}{|\vec{a} \times \vec{b}|^2 + |\vec{c}|^2 \rho_c^2} \quad (3.41)$$

Putting this into Eq. 3.26:

$$g_k(\eta, \psi, \zeta, l, \phi) = g_f \left[ f_t(\phi, \zeta) \right] \left[ \frac{(|\vec{a}| + |\vec{b}|)(|\vec{a}||\vec{b}| - \vec{a} \cdot \vec{b})}{|\vec{a}||\vec{b}|(|\vec{a} \times \vec{b}|^2 + |\vec{c}|^2 \rho_c^2)} \right] (\vec{a} \times \vec{b})_k \quad (3.42)$$

For the other vortex-core models, Eq. 3.41 is used to provide  $\rho$  for the appropriate  $\gamma_c(\rho)$  function. For large  $\rho$  (typically,  $\rho > 10^4$ )  $\gamma_c(\rho)$  can be set equal to 1.0 to save computation.

A close blade-vortex interaction can change  $F_c$  in two ways. It can cause tip vortex bursting, which enlarges  $\rho_c$  and hence changes  $\gamma_c(\rho)$ , or it can change  $q_f$ . The first step is to determine whether or not a particular tip vortex-line segment has had a close blade-vortex interaction. Consider a top view (projected into the TPP) of the tip vortex-line segment (with circulation  $\Gamma$ ) and the  $\eta$  blade (Fig. 17). Define point  $P_c$  as the point on the vortex-line segment (or its extension) which intersects the  $\eta$  blade (or its extension) in this TPP projection. Let  $\eta_c$  be the radial station on the  $\eta$  blade of point  $P_c$ . The first requirement for a close blade-vortex interaction is that the point  $P_c$  lies on the  $\eta$  blade in the TPP projection. Assuming a 10% blade root cutout and providing a small margin at the tip, this means that  $\eta_c$  must be

$$0.10 \leq \eta_c \leq 1.01 \quad (3.43)$$

The magnitude of  $\eta_c$  can be found with the use of Fig. 17 and some manipulation:

$$\eta_c = \frac{x_a y_b - x_b y_a}{\Delta y \sin \psi - \Delta x \cos \psi} + \eta \quad (3.44)$$

where:

$$\Delta x = x_b - x_a \quad (3.45)$$

$$\Delta y = y_b - y_a \quad (3.46)$$

Notice that the numerator is equal to  $(axb)_k$ , which must be calculated in any case as part of Eq. 3.26.

Define the distance from point  $P_c$  to point  $P_a$  in the TPP projection as  $\Delta l_{xy}$  (normalized by vortex-line segment length). Point  $P_a$  is at the end of the tip vortex-line segment which has that largest azimuth angle  $\phi$ . The sign of  $\Delta l_{xy}$  is positive when point  $P_a$  is behind the  $\eta$  blade, as shown in Fig. 17:

$$\Delta l_{xy} = \frac{y_a - \Delta \eta \cos \psi}{\Delta y} = \frac{x_a - \Delta \eta \sin \psi}{\Delta x} \quad (3.47)$$

where:

$$\Delta \eta = \eta_c - \eta \quad (3.48)$$

Two versions of the  $\Delta l_{xy}$  formula are given because either  $\Delta x$  or  $\Delta y$  can be zero.

The second requirement for a close blade-vortex interaction is that the nearest end of the tip vortex-line segment be no more than one segment length behind the  $\eta$  blade ( $\Delta l_{xy} < 1.0$ ) or more than one-half the segment length ahead of the  $\eta$  blade ( $\Delta l_{xy} > -1.5$ ).

$$-1.5 < \Delta l_{xy} < 1.0 \quad (3.49)$$

This is a generous definition and could be restricted further if desired.

The two requirements outlined above are sufficient to require the use of the factor  $q_f$  to represent the close blade-vortex interaction; the penalty for computing the factor  $q_f$  when it is not really needed is extra computation, not incorrect results. For the vortex bursting case, more stringent criteria must be met because bursting at the wrong time gives incorrect results. The

first requirement remains, as stated in Eq. 3.43. The second requirement is restricted further in the area ahead of the  $\eta$  blade, since bursting is expected to occur at or behind the  $\eta$  blade:

$$DVB < \Delta l_{xy} < 1.0 \quad (3.50)$$

where DVB is an input to LDS-73. A typical value for DVB is zero. This implies that all of the tip vortex-line segment is behind the  $\eta$  blade.

The bursting model requires that all of a tip vortex-line segment be burst or none of it. This tends to cause the choice of a smaller DVB than would otherwise be used. For example, suppose that the theory says the tip vortex-line should burst at  $\Delta l_{xy} = 0.10$  and that point  $P_a$  is at  $\Delta l_{xy} = 0.05$ . Ideally, 95% of the segment should be burst and 5% not. A DVB = 0.10 would cause no bursting while a DVB = 0.0 would cause 100% bursting. The latter choice is probably best, pending a more complex model which allows partial bursting of a segment.

This leaves the case where part of the tip vortex-line segment has passed the  $\eta$  blade, but not enough to make  $\Delta l_{xy} > DVB$ . This segment will not burst immediately, but will burst later on. To provide for this case, the age at which the segment bursts  $\delta_b(\phi)$  is increased by  $\Delta\phi$  for every increment of 0.5 (or fraction thereof), that  $\Delta l_{xy}$  is less than DVB.

A third requirement for tip vortex-line segment bursting is that the segment (or its extension) pass within a distance  $FVB \cdot \rho_c$  below (or above) the  $\eta$  blade. Define  $z_c$  as the distance of point  $P_c$  (on the tip vortex-line segment or its extension) from the  $\eta$  blade (Fig. 18). Since point  $P_c$  lies on the  $\eta$  blade in the TPP projection (Fig. 17),  $z_c$  is a distance perpendicular to the TPP. From Fig. 18:

$$z_c = z_a + a \cdot \Delta\eta - \Delta l_{xy} (z_b - z_a) \quad (3.51)$$

Now the third requirement can be written:

$$FVB \geq |z_c / \rho_c| \quad (3.52)$$

The absolute value is necessary because the segment can be either above or below the  $\eta$  blade.

To summarize the tip vortex core bursting criteria, consider a tip vortex-line segment identified by azimuth angle  $\phi$  and age  $\delta$ . If the basic criteria of Eqs. 3.43, 3.50, and 3.52 are all met, then bursting occurs immediately:

$$\delta_b(\phi) = \delta \quad (3.53)$$

If Eq. 3.50 is not satisfied, but Eq. 3.49 is, then

$$\delta_b(\phi) = \begin{cases} \delta + \Delta\phi & \text{for } 0 < (\text{DVB} - \Delta l_{xy}) < 0.5 \\ \delta + 2\Delta\phi & \text{for } 0.5 < (\text{DVB} - \Delta l_{xy}) < 1.0 \\ \delta + 3\Delta\phi & \text{for } 1.0 < (\text{DVB} - \Delta l_{xy}) < 1.5 \end{cases} \quad (3.54)$$

Assuming that Eqs. 3.43 and 3.49 are satisfied for a particular tip vortex-line segment, it becomes necessary to compute  $q_f$ . This  $q_f$  represents the effects of the extra near wake generated by a close blade-vortex interaction. The effects are estimated using a lifting surface solution by Johnson [52,53], see Subsection 2.5.2. The expression for  $q_f$  used in LDS-73 is a simplified one, specialized to Mach number ( $M$ ) of zero. For a more general  $M \neq 0$  case, the use of Johnson's Eq. 40 [53] is suggested. This expression is very complex and will not be repeated here. However, the necessary data to use this expression and the relationship of Johnson's notation to the notation used here will be given.

The form of Johnson's Eq. 40 is

$$\frac{L \sqrt{1-M^2}}{2\pi\rho V^2 b} = \frac{\Gamma}{2\pi V b} \left\{ - \right\} \quad (3.55)$$

To get  $q_f$ , the lift (L) given by Eq. 3.55 must be divided by the lift ( $L^*$ ), computed neglecting lifting-surface theory or the near wake. Consider an infinite, straight vortex line of circulation  $\Gamma$  passing below the  $\eta$  blade, parallel to the TPP, at a distance  $z_c$  and making an angle  $\Lambda$  with the  $\eta$  blade (Fig. 19). A portion of this infinite vortex line is designated the vortex-line segment and has a  $\Delta x$  and a  $\Delta y$  just like the segment of Fig. 17. The definitions of  $\psi$ ,  $\Delta\eta$ , point  $P_\eta$ , and point  $P_c$  in Fig. 19 are the same as in Fig. 17. Now, using the Biot-Savart relation for an infinite, straight vortex line, the  $z$  component of the induced velocity at point  $P_\eta$  is

$$q_k^* = \frac{\Gamma}{4\pi R} \left[ \frac{2 \Delta\eta \cos \delta}{z_c^2 + (\Delta\eta \cos \delta)^2} \right] \quad (3.56)$$

Assuming that the angle of attack  $\alpha$  is a small angle,

$$L^* = \frac{1}{2} \rho V^2 c \frac{a}{\sqrt{1-M^2}} \alpha = \rho V b \frac{a}{\sqrt{1-M^2}} q_k^* \quad (3.57)$$

where  $b$  is the semi-chord ( $c/2$ ) and  $a/\sqrt{1-M^2}$  is the lift curve slope ( $\partial C_L / \partial \alpha$ ). Now

$$\frac{L^* \sqrt{1-M^2}}{2\pi \rho V^2 b} = \left( \frac{a}{2\pi} \right) \left( \frac{b}{R} \right) \frac{\Gamma}{2\pi V b} \left[ \frac{\Delta\eta \cos \delta}{z_c^2 + (\Delta\eta \cos \delta)^2} \right] \quad (3.58)$$

Dividing Eq. 3.55 by Eq. 3.58 to obtain  $q_f = L/L^*$ ,

$$q_f = \left( \frac{2\pi}{a} \right) \left( \frac{R}{b} \right) \left[ \frac{z_c^2 + (\Delta\eta \cos \delta)^2}{\Delta\eta \cos \delta} \right] \left\{ - \right\} \quad (3.59)$$

where the expression  $\{-\}$  is the  $\{-\}$  expression in Johnson's Eq. 40 [53].

To compute the  $\{-\}$  expression, the following inputs are needed (in Johnson's notation):  $r^A$ ,  $h$ ,  $\Lambda$ . The lengths  $r^A$  and  $h$  are both normalized by the semi-chord ( $b$ ). In terms of the notation used here:

$$r^A = -\Delta\eta (R/b) \quad (3.60)$$

$$h = |z_c| (R/b) \quad (3.61)$$

$$\Lambda = \frac{\pi}{2} + \delta \quad (3.62)$$

Now  $\Lambda$  and  $\delta$  can be calculated (Fig. 19):

$$\sin\Lambda = \cos\delta = \frac{\Delta y \sin\psi - \Delta x \cos\psi}{\sqrt{\Delta x^2 + \Delta y^2}} \quad (3.63)$$

$$\cos\Lambda = -\sin\delta = -\frac{\Delta y \cos\psi + \Delta x \sin\psi}{\sqrt{\Delta x^2 + \Delta y^2}} \quad (3.64)$$

This completes the computation of  $q_f$  and of  $F_c$ .

### 3.2.5 Inboard Trailing Wake

The computation of inboard-trailing-wake induced velocities is similar to that for the tip vortex but much simpler. Since the inboard trailing wake does not involve a concentrated vortex line, such as the tip vortex, the use of a rigid-wake geometry is adequate. Also, the close blade-vortex interaction effects of vortex core bursting and of the lifting-surface solution can be neglected. Thus, the inboard trailing wake is modeled by a rigid wake vortex line, with an artificially enlarged vortex core, or by a rigid wake vortex sheet, see Subsection 2.6.

The  $x, y, z$  coordinate system defined for the tip vortex in Subsection 3.2.3 is also used here. The  $\hat{a}$  and  $\hat{b}$  definitions for the rigid wake tip vortex (Eqs. 3.9 to 3.16) also apply with an appropriate choice of  $l$ . For a vortex line model  $l$  is  $l_2$  (an input) and for a vortex sheet model  $l$  is  $l_i(\phi)$  (also an input). This definition of  $\hat{a}$  and  $\hat{b}$  means that the circulation  $\gamma_a$  of an inboard trailing-wake segment must be the negative of the  $\gamma_a$  for the corresponding tip-vortex segment, see Subsection 2.8.

For a vortex-line model, the vortex-core radius  $\rho_i$  is chosen

to be about half the width of the average inboard trailing vortex sheet. This is done through the choice of  $\ell_2$  since:

$$\rho_i = \ell_2 - \ell_1 \quad (3.65)$$

Now,  $q_k(\eta, \psi, \zeta, \ell, \phi)$  can be computed from Eq. 3.26. For this case,  $F_c$  is  $\gamma_c(\rho)$ , which is normally given by Eq. 2.3 (with  $\rho_c = \rho_i$ ), and  $f_t(\phi, \delta)$  is replaced by  $(-1.0)$  which represents the minus sign on  $\gamma_a$  discussed above.

For a vortex-sheet model, a vortex-core radius  $\rho_{vs}$  can be used, if desired. The length of the vortex-sheet segment ( $\Delta\tilde{x}$ ) is:

$$\Delta\tilde{x} = \ell_i(\phi) - \ell_1 \quad (3.66)$$

The  $z$  coordinate of the midpoint of the back edge of the vortex-sheet segment ( $z_m$ ) is the average of  $z_a$  and  $z_b$  computed from Eqs. 3.15 and 3.16 with  $\ell = \ell_1$ :

$$z_m = \lambda(\delta + \Delta\phi/2) - a_o(\ell_1 - \eta) \quad (3.67)$$

Now  $q_k(\eta, \psi, \zeta, \ell, \phi)$  can be computed in the same way as for the tip vortex sheet case but with the  $[1 - f_t(\phi, \delta)]$  factor replaced by minus one to represent the minus sign of  $\gamma_a$ . The analog of Eq. 3.29 for the inboard trailing vortex sheet instead of the tip vortex is

$$q_k(\eta, \psi, \zeta, \ell_2, \phi) = - (I_1 z_x + I_2 z_z) \quad (3.68)$$

The near inboard trailing vortex sheet case must be handled specially in the same way that the near tip vortex sheet is handled. For this case:

$$c_b = \Delta\phi \ell_i(\phi) \quad (3.69)$$

$$x_1 = \ell_i(\phi) - \eta \quad (3.70)$$

$$x_2 = \ell_1 - \eta \quad (3.71)$$

Now  $q_k(\eta, \psi, \zeta, \ell_2, \phi)$  is computed using Eqs. 3.36, 3.37, or 3.38 as necessary, but with the  $[1 - f_t(\phi, \delta)]$  factor replaced by  $(-1.0)$ .

### 3.2.6 Shed Wake

The computation of shed-wake induced velocities is similar, in principle, to the trailing wake, but differs in detail. Like the inboard trailing wake, there is no concentrated vortex line in the shed wake and the effects of vortex core bursting and of the lifting surface solution can be neglected. Again, the rigid-wake geometry is adequate; however, as a matter of convenience, the outboard end of the shed wake is located on the tip vortex, even when the tip vortex is distorted. For airloads computations in LDS-73, only the vortex-line shed-wake model is used. Vortex-sheet, shed-wake models have been tried in earlier programs and the results were very similar to those of the vortex-line model at greatly increased expense.

The standard  $x, y, z$  coordinate system is used (see Sub-section 3.2.3). Point  $P_a$  is at the outboard end of the shed-vortex-line segment and point  $P_b$  is at the inboard end. To save extra computation, the  $\vec{a}$  for the shed-vortex line is the same as the  $\vec{a}$  for the tip vortex line (Eqs. 3.11, 3.13, 3.15 or 3.18, 3.20, 3.22). If the distorted-wake model is used for the tip vortex, this means that the outboard end of each shed-wake segment will be located by the distorted wake model. The inboard end of each shed-wake segment is always located by the rigid wake model with  $\ell = \ell_2$ :

$$x_b = \ell_2 \sin \phi - \eta \sin \psi \quad (3.72)$$

$$y_b = \ell_2 \cos \phi - \eta \cos \psi + \mu \delta \quad (3.73)$$

$$z_b = \lambda \delta - a_0(\ell_2 - \eta) \quad (3.74)$$

The circulation of each shed-wake vortex-line segment is  $\gamma_s(\phi)$ , (Eq. 2.9). The vortex-core radius  $\rho_s$  is chosen to approximately fill the space between adjacent shed-vortex-line segments, thus approximating a continuous vortex sheet:

$$\rho_s = 0.4 \Delta\phi \quad (3.75)$$

For the shed wake the correction factor  $F_c$  is simply  $\gamma_c(\rho)$ , which is normally given by Eq. 2.3 (with  $\rho_c = \rho_s$ ). The factor  $f_t(\phi, \delta)$  is always one for the shed wake. Recall that the shed wake is identified by  $\ell_1$ ; therefore  $q_k(\eta, \psi, \zeta, \ell_1, \phi)$  is computed from Eq. 3.26 with the appropriate  $F_c$ ,  $f_t(\phi, \delta)$ ,  $\hat{a}$ , and  $\hat{b}$ .

The near shed wake is normally represented by a vortex sheet. This vortex sheet starts a distance  $\epsilon_s$  behind the points  $P_\eta$  on the  $\eta$  blade and extends over the first  $\Delta\phi$  interval (see Subsection 2.7). Recall the definition of the shed circulation  $\gamma_s(\phi)$ :

$$\gamma_s(\phi) = \gamma_{br}(\phi + \Delta\phi) - \gamma_{br}(\phi) \quad (2.9)$$

For the far shed wake, all of the wake shed between  $\phi$  and  $\phi + \Delta\phi$  is accumulated into a shed-vortex line at  $\phi$ . For the near shed wake, it is spread out in a sheet between  $\phi + \Delta\phi$  and  $\phi$ . The geometry of the sheet is referred to the  $\eta$  blade which is at  $\psi = \phi + \Delta\phi$ . This is awkward because  $\hat{a}$  and  $\hat{b}$  are defined at  $\phi$  for use in the trailing wake computations, but not at  $\phi + \Delta\phi$ . To avoid defining an extra set of  $\hat{a}$  and  $\hat{b}$  at  $\phi + \Delta\phi$ , the computation of the near shed-wake segment is in LDS-73 deferred one  $\Delta\phi$ -step until  $\psi = \phi$ . Thus,  $\gamma_s(\phi - \Delta\phi)$  must be used for the circulation of the near shed-wake segment. This allows the far shed-wake equations for  $\hat{a}$  and  $\hat{b}$  to be used for the near shed wake, with an extra term to include the effect of  $\epsilon_s$ . For  $x_a$  and  $x_b$ , subtract  $\epsilon_s \cos\psi$ . For  $y_a$  and  $y_b$ , add  $\epsilon_s \sin\psi$ . For  $z_a$  and  $z_b$ , the age  $\delta$  is equal to  $\epsilon_s$ .

In addition to  $\hat{a}$  and  $\hat{b}$ , the vortex-sheet computation requires  $\Delta\tilde{x}$  and  $z_m$ . The length of the vortex-sheet segment ( $\Delta\tilde{x}$ ) is

defined by the distance between adjacent shed vortex lines, at their midpoints, with a correction for  $\epsilon_s$ :

$$\Delta \tilde{x} = \frac{\Delta \phi}{2} (l_3 - l_2) - \epsilon_s \quad (3.76)$$

The  $z$  coordinate of the midpoint of the back edge of the sheet segment ( $z_m$ ) is the average of  $z_a$  and  $z_b$  for  $\phi - \Delta \phi$ . Now,  $q_k(\eta, \psi, \zeta, l, \phi)$  can be computed in the same way as for the tip vortex sheet, but with  $[1 - f_t(\phi, \delta)]$  replaced by plus one. The analog of Eq. 3.29 for the near shed wake is

$$q_k(\eta, \psi, \zeta, l, \phi) = (I_1 z_x + I_2 z_z) \quad (3.77)$$

### 3.2.7 Special Cases

There are three special cases arising during induced-velocity computations and not covered elsewhere. They are: avoidance of the singularity at the edge of a vortex sheet, limitation of the maximum angle-of-attack change ( $\Delta \alpha_m$ ), due to any wake element, and the consideration of tangential induced velocities.

It is shown in Appendix B (Subsection B.1) that there is a singularity when point  $P_\eta$  approaches the edges of a vortex-sheet segment (i.e., when  $x_1 \rightarrow 0$  or  $x_2 \rightarrow 0$ ). This singularity is a result of the vortex-sheet segment model where the circulation drops sharply from a finite value to zero as a step function at the edges. In reality the circulation would either taper off to zero gradually or would continue, without a break, into the adjacent segment. Either way there is no singularity in reality. A more accurate vortex sheet model of reality would therefore avoid the singularity. This would be very complicated and expensive, however, and the simpler solution of avoiding the edges is adopted.

Point  $P_\eta$  is accurately fixed on the rotor blade. On the other hand, the edges of the vortex-sheet segments, with the exception of the near-wake case, are located rather arbitrarily by the requirements of the plane, rectangular, vortex-sheet-segment model. Thus, these edges can be moved to avoid the singularity without particularly changing the accuracy of the model. In LDS-73, the values of

$x_1^2$  and  $x_2^2$  are checked to see if they are greater than  $(VSM \cdot \Delta \tilde{x})^2$ , where the vortex-sheet margin (VSM) is an input (typically 0.1 or 0.2). If either  $x_1$  or  $x_2$  is not large enough, then it is increased to  $VSM \cdot \Delta \tilde{x}$ .

As a result of some investigations by Ham [54,55], it is postulated that there is a maximum incremental lift coefficient  $\Delta C_{L_{\max}}$ , due to any blade-vortex interaction of 0.2 to 0.3. This corresponds to a maximum change in angle of attack  $(\Delta \alpha_{\max})$  of 0.035 to 0.052 radians. The LDS-73 program does not isolate each individual blade-vortex interaction but instead considers one vortex line (or sheet) segment at a time. Fortunately, in most cases, the major portion of the induced velocity contribution of a blade-vortex interaction comes from one tip vortex-line segment. The change in angle of attack at point  $P_\eta$  ( $\Delta \alpha$ ), due to each tip vortex-line segment is readily calculated. Assuming that  $\Delta \alpha$  is a small angle,

$$\Delta \alpha = \gamma_a \left( \frac{b}{2R} \right) q_k(\eta, \psi, \zeta, \ell_3, \phi) / U_T(\eta, \psi) \quad (3.78)$$

where  $U_T(\eta, \psi)$  is the tangential component of velocity at point  $P_\eta$  (Fig. 20). If  $\Delta \alpha$  is greater than  $\Delta \alpha_{\max}$ , then  $q_k(\eta, \psi, \zeta, \ell_3, \phi)$  is multiplied by  $(\Delta \alpha_{\max} / \Delta \alpha)$  which reduces  $\Delta \alpha$  to  $\Delta \alpha_{\max}$ . Since  $\Delta \alpha_{\max}$  is an input to LDS-73, various values can be tested.

Normally, only the  $z$  component (perpendicular to the TPP) of the induced velocity ( $q_k$ ) is considered in airloads computations. This is because the induced velocity is frequently an important part of the total downwash  $\lambda(\eta, \psi)$ . On the other hand, the induced contribution ( $q_T$ ) to the tangential velocity  $U_T(\eta, \psi)$  is normally assumed to be small compared to the contribution of the helicopter airspeed and the rotor rotation  $(\eta + \mu \sin \psi)$ . To test the importance of  $q_T$ , provision to compute it has been made in LDS-73. This is easily done using  $q_k$  and the components of  $\vec{a} \times \vec{b}$ , which is a vector parallel to the induced velocity (Appendix A, Eq. A.22):

$$q_t(\eta, \psi, \zeta, l, \phi) = q_i \sin \psi - q_j \cos \psi \quad (3.79)$$

$$q_i = q_k(\eta, \psi, \zeta, l, \phi) * (a \times b)_i / (a \times b)_k \quad (3.80)$$

$$q_j = q_k(\eta, \psi, \zeta, l, \phi) * (a \times b)_j / (a \times b)_k \quad (3.81)$$

To save computation time, a QTAN( $\eta, \psi, \phi$ ) matrix is defined which is analogous to the QMAT( $\eta, \psi, \phi$ ) matrix:

$$QTAN(\eta, \psi, \phi) = \sum_{\zeta} \sum_{n=0}^{m-1} \left[ \sum_{l=l_2}^{l_3} q_t(\eta, \psi, \zeta, l, \phi + 2\pi n) + q_t(\eta, \psi, \zeta, l, \phi - \Delta\phi + 2\pi n) - q_t(\eta, \psi, \zeta, l, \phi + 2\pi n) \right] \quad (3.82)$$

The total tangential component of induced velocity at point  $P_\eta$  is obtained by summing QTAN( $\eta, \psi, \phi$ ) over  $\phi$ :

$$q_T(\eta, \psi) = \left( \frac{b}{2R} \right) \sum_{\phi} \left[ \gamma_{bw}(\phi) * QTAN(\eta, \psi, \phi) \right] \quad (3.83)$$

Finally,

$$U_T(\eta, \psi) = \eta + \mu \sin \psi + q_T(\eta, \psi) \quad (3.84)$$

In LDS-73, both  $q_T(\eta, \psi)$  and  $(\eta + \mu \sin \psi)$  are always computed and printed out side-by-side for comparison. There are three options in the airloads computation:

- 1)  $q_T(\eta, \psi)$  is neglected in  $U_T(\eta, \psi)$
- 2)  $q_T(\eta, \psi)$  is included in  $U_T(\eta, \psi)$
- 3) two sets of airloads are computed using (1) and (2) for comparison.

Normally option (1) is used because  $q_T(\eta, \psi)$  is not very important.

### 3.3 Blade Motion

Blade motion is only important in helicopter rotor airloads computations to the extent that it influences the airloads. Blade motion influences the airloads when it is of large enough amplitude to change the local angle of attack of a rotor-blade section. At low advance ratios the modes of blade motion which have a significant effect on airloads are rigid-body flapping and first mode flapwise bending. At higher advance ratios, blade torsional motion can also become important. Since the work reported here is primarily concerned with low advance ratios, where tip-vortex distortion is important, blade-torsional motion is neglected. For a more general airloads computation, torsional motion should be included.

If blade stresses are to be computed, many more modes of blade motion need to be considered. It is suggested that this is best done by developing a separate dynamics program which includes a complete blade motion analysis but which uses airloads computed by a separate program similar to LDS-73. This decoupling of the small amplitude blade motion from the airloads saves a substantial amount of computation. No such dynamics program has been developed to go with LDS-73, since blade stresses are not the object of the work reported here.

Two different solutions for the blade motion are used in LDS-73. The harmonic solution considers only the zeroth, first, and second harmonics of rigid-body flapping and neglects blade bending. The numerical solution includes all harmonics of rigid-body flapping and of the first mode of flapwise blade bending. The harmonic solution is much simpler and faster and it is used to provide a starting point for the iteration required by the more accurate numerical solution. The harmonic solution is also useful because it is possible to isolate the various contributions to the flapping motion from: thrust, blade twist, and the individual downwash harmonics. This data can provide a useful insight into the sources of error in the computed flapping motion.

Rotor trim is specified by thrust coefficient ( $C_T$ ) and TPP incidence ( $i$ ) in both solutions. The thrust ( $T$ ) is assumed to act perpendicular to the tip-path plane (TPP) and to be the vector sum of the weight ( $W$ ) and the propulsive force ( $X$ ):

$$T = \sqrt{W^2 + X^2} \quad (3.85)$$

The incidence of the TPP to the relative wind  $i$  (Fig. 15) is:

$$i = \sin^{-1} (X / T) \quad (3.4)$$

The LDS-73 program computes the horizontal force coefficient ( $C_H$ ) so that it can be compared to  $C_T$ . As long as  $C_H$  is much less than  $C_T$ , the assumption that the thrust is perpendicular to the TPP is valid.

Other rotor trim parameters such as collective pitch and the flapping harmonics are computed by requiring equilibrium at the flapping hinge and by requiring that the input  $C_T$  and  $i$  be obtained. This approach gives the orientation of the rotor with respect to the relative wind, but it ignores the shaft and the fuselage. This is satisfactory because the orientation of the shaft and the fuselage are not needed in rotor airloads computations.

The harmonic solution for blade motion assumes that the lift-curve slope  $\partial C_L / \partial \alpha$  is constant. This means that the compressibility correction to the lift can only be included in an average way, based on conditions at the 75% radius, and that stall is neglected. In the numerical solution,  $\partial C_L / \partial \alpha$  is not held constant so compressibility and static-stall effects can be included. Dynamic-stall effects are not properly represented in the numerical solution, due to the difficulty of accurately estimating  $\dot{\alpha} = \partial \alpha / \partial \psi$ . Dynamic stall could be included in a completely revised version of the numerical solution, if necessary.

It must be emphasized that the primary importance of blade motion in airloads computations is the requirement for flapping

equilibrium. This requirement causes a substantial redistribution of the rotor airloads and its importance increases with advance ratio ( $\mu$ ). Any forward flight airloads computation should include enough of a blade-motion solution to satisfy flapping equilibrium. Any further refinements in the blade-motion solution depend on the accuracy required and the flight conditions considered; i.e., high advance ratios require more sophisticated blade motion solutions.

### 3.3.1 Harmonic Solution

The fundamental assumption of the harmonic solution is that the blade motion consists of zeroth, first, and second harmonic rigid-body flapping:

$$\beta(\psi) = a_0 - a_1 \cos \psi - b_1 \sin \psi - a_2 \cos 2\psi - b_2 \sin 2\psi \quad (3.86)$$

The downwash  $\lambda(\eta, \psi)$ , which was computed in Subsection 3.2, is also represented by its harmonics:

$$\begin{aligned} \lambda(\eta, \psi) = & \lambda_0(\eta) + \lambda_{1c}(\eta) \cos \psi + \lambda_{1s}(\eta) \sin \psi \\ & + \lambda_{2c}(\eta) \cos 2\psi + \lambda_{2s}(\eta) \sin 2\psi + \dots \end{aligned} \quad (3.87)$$

Using these expressions for  $\beta$  and  $\lambda$  while requiring flapping equilibrium and the achievement of a given  $C_T$  leads to a set of algebraic equations for the harmonics of  $\beta$  and the collective pitch  $\theta_0$ .

The equation for moment equilibrium about an offset flapping hinge is:

$$I_b \frac{d^2 \beta}{dt^2} + I_b \Omega^2 \beta = R^2 \int_{\lambda_1}^{\lambda_0} (\eta - \epsilon) L(\eta, \psi) d\eta \quad (3.88)$$

where  $I_b$  is the rotor blade flapwise moment of inertia about the flapping hinge,  $L(\eta, \psi)$  is the airload per unit span at point  $P_\eta$ , and  $(\eta - \epsilon)$  is the moment arm of  $L(\eta, \psi)$  about the flapping hinge. Figure 21 clarifies the definition of the flapping hinge offset  $\epsilon$  (normalized by  $R$ ).

The airload per unit span at point  $P_\eta$  can be written:

$$L(\eta, \psi) = \frac{1}{2} \rho a c (\Omega R)^2 \left[ F U_T^2 \alpha + \left( \frac{1-F}{2\pi} \right) \int_0^{2\pi} U_T^2 \alpha d\psi \right] \quad (3.89)$$

The lift deficiency function  $F$  is an alternate way of modeling the shed wake and is normally not used ( $F=1.0$ ). The second term in Eq. 3.89 is because  $F$  does not apply to the steady-state component of  $L(\eta, \psi)$ . The tangential and perpendicular components of the airspeed  $U$  in the blade section plane at point  $P_\eta$  are  $U_T$  and  $U_P$ , respectively when normalized by tip speed (Fig. 20). For helicopters  $U_T$  is normally either much greater than  $U_P$  or  $U$  is so small that the dynamic pressure is too small to cause significant airloads. Therefore  $U_P^2$  is neglected compared to  $U_T^2$  in the harmonic solution. This is why  $U_T^2$  is used instead of  $U^2$  for the dynamic pressure in Eq. 3.89.

Before substituting Eq. 3.89 into Eq. 3.88, it is helpful to normalize. Define Lock Number (LN) as:

$$LN \equiv \frac{2\pi \rho c R^4}{I_b} \quad (3.90)$$

Instead of time  $t$  use azimuth angle  $\psi$  and define:

$$\dot{\beta} = \frac{d\beta}{d\psi} = \frac{1}{\Omega} \frac{d\beta}{dt} \quad (3.91)$$

$$\ddot{\beta} = \frac{d^2\beta}{d\psi^2} = \left( \frac{1}{\Omega} \right)^2 \frac{d^2\beta}{dt^2} \quad (3.92)$$

Now substituting into Eq. 3.88 and dividing by  $I_b \Omega^2$ :

$$\ddot{\beta} + \beta = \left( \frac{a}{2\pi} \right) \left( \frac{LN}{2} \right) \int_0^{1.0} \left[ F U_T^2 \alpha + \left( \frac{1-F}{2\pi} \right) \int_0^{2\pi} U_T^2 \alpha d\psi \right] d\eta \quad (3.93)$$

This is the equation requiring moment equilibrium about the flapping hinge. The requirement for a given thrust coefficient  $C_T$  is obtained by integrating the airloads over the rotor:

$$C_T = \frac{\sigma a}{4\pi} \int_0^{2\pi} \int_{l_1}^{l_2} U_T^2 \alpha d\eta d\psi \quad (3.94)$$

where  $\sigma$  is the rotor solidity. These equations (3.93 and 3.94) can be solved for the flapping  $\beta(\psi)$  and the collective pitch  $\theta_0$ . Before this can be done, expressions for  $U_T(\eta, \psi)$  and  $\alpha(\eta, \psi)$  must be developed.

The angle of attack  $\alpha(\eta, \psi)$  can be written (Fig. 20):

$$\alpha(\eta, \psi) = \theta(\eta) - \tan^{-1}(U_p/U_T) \quad (3.95)$$

The pitch  $\theta(\eta)$  is not a function of azimuth  $\psi$  because the blade motion solution is done in the no-feathering plane (NFP), which eliminates cyclic pitch, and because blade-torsional motion is neglected. For the harmonic solution, a linear twist is assumed:

$$\theta(\eta) = \theta_0 + \theta_1 \eta \quad (3.96)$$

Again, neglecting  $U_p^2$  compared to  $U_T^2$ , the angle of attack can be written:

$$\alpha(\eta, \psi) = \theta_0 + \theta_1 \eta - U_p/U_T \quad (3.97)$$

For the harmonic solution, the induced contribution to the tangential airspeed is neglected. Therefore:

$$U_T(\eta, \psi) = \eta + \mu \sin \psi \quad (3.98)$$

Assuming that the flapping  $\beta$  is a small angle:

$$U_p = \lambda(\eta, \psi) + \mu a_1 + \beta \mu \cos \psi + (\eta - \varepsilon) \dot{\beta} \quad (3.99)$$

The  $\mu a_1$  term is the increment to  $\lambda(\eta, \psi)$  caused by going from the TPP to the NFP and is analogous to the  $\mu \tan i$  component of  $\lambda(\eta, \psi)$ , see Fig. 15.

All of the elements needed to solve Eqs. 3.93 and 3.94 are now available. The procedure starts with the development of an expression for  $U_T^2 \alpha$ . Substituting Eq. 3.97:

$$U_T^2 \alpha = U_T^2 (\theta_0 + \theta_1 \eta) - U_T U_P \quad (3.100)$$

Substituting Eq. 3.98 for  $U_T$  and Eq. 3.99 for  $U_P$  into Eq. 3.100:

$$U_T^2 \alpha = (\theta_0 + \theta_1 \eta) (\eta + \mu \sin \psi)^2 - (\eta + \mu \sin \psi) \left[ \lambda(\eta, \psi) + \mu a_1 + \beta \mu \cos \psi + (\eta - \varepsilon) \dot{\beta} \right] \quad (3.101)$$

Now, Eq. 3.86 can be differentiated to obtain  $\dot{\beta}$  and  $\ddot{\beta}$ :

$$\dot{\beta} = a_1 \sin \psi - b_1 \cos \psi + 2a_2 \sin 2\psi - 2b_2 \cos 2\psi \quad (3.102)$$

$$\ddot{\beta} = a_1 \cos \psi + b_1 \sin \psi + 4a_2 \cos 2\psi + 4b_2 \sin 2\psi \quad (3.103)$$

Next, Eqs. 3.86, 3.87, and 3.102 for  $\beta$ ,  $\lambda(\eta, \psi)$ , and  $\dot{\beta}$ , respectively are substituted into Eq. 3.101. The resulting expression for  $U_T^2 \alpha$  is substituted into Eqs. 3.93 and 3.94. Finally, Eq. 3.86 for  $\beta$  and Eq. 3.103 for  $\ddot{\beta}$  are substituted into Eq. 3.93.

The final versions of Eq. 3.93 and Eq. 3.94, after all of these substitutions, are very lengthy and will not be reproduced here. These equations involve products of the form  $\sin n\psi \sin m\psi$ ,  $\cos n\psi \cos m\psi$ , or  $\sin n\psi \cos m\psi$ . These products are eliminated by the following trigonometric relations:

$$\sin(n\psi) \sin(m\psi) = \frac{1}{2} [\cos(n-m)\psi - \cos(n+m)\psi] \quad (3.104)$$

$$\cos(n\psi) \cos(m\psi) = \frac{1}{2} [\cos(n-m)\psi + \cos(n+m)\psi] \quad (3.105)$$

$$\sin(n\psi) \cos(m\psi) = \frac{1}{2} [\sin(n-m)\psi + \sin(n+m)\psi] \quad (3.106)$$

This leaves  $\sin n\psi$  or  $\cos n\psi$  as the only function of  $\psi$  in any individual term. To ensure that  $n$  is non-negative, use the relations:

$$\sin(-n\psi) = -\sin(n\psi) \quad (3.107)$$

$$\cos(-n\psi) = \cos(n\psi) \quad (3.108)$$

It is only necessary to retain terms for which  $n$  is less than 3 and the number of  $\lambda(\eta, \psi)$  harmonics used is varied to ensure that all terms having  $n < 3$  are included.

For Eq. 3.94, the azimuth integral eliminates all  $\sin n\psi$  and  $\cos n\psi$  terms, except for  $\cos n\psi$  when  $n = 0$ . This leaves:

$$C_T = \frac{\nabla a}{2} \int_{-1}^{+1} \left[ \left( \frac{\mu^2 \theta_0}{2} - \frac{\mu}{2} \lambda_{1s} + \frac{\mu^2 b_2}{4} + \frac{\varepsilon \mu a_1}{2} \right) + \left( \frac{\mu^2 \theta_1}{2} - \lambda_0 - \mu a_1 + \frac{\varepsilon \mu a_1}{2} \right) \eta + \theta_0 \eta^2 + \theta_1 \eta^3 \right] d\eta \quad (3.109)$$

All of the terms not containing any harmonics of  $\lambda(\eta, \psi)$  can be integrated over  $\eta$ :

$$C_T = \frac{\nabla a}{2} \left[ \left( \frac{\mu^2 \theta_0}{2} - \frac{\mu^2 b_2}{4} + \frac{\varepsilon \mu a_1}{2} \right) (1 - l_1) + \left( \frac{\mu^2 \theta_1}{2} - \mu a_1 + \frac{\varepsilon \mu a_1}{2} \right) \left( \frac{1 - l_1^2}{2} \right) + \theta_0 \left( \frac{1 - l_1^3}{3} \right) + \theta_1 \left( \frac{1 - l_1^4}{4} \right) - \int_{-1}^{+1} \left( \frac{\mu}{2} \lambda_{1s} + \eta \lambda_0 \right) d\eta \right] \quad (3.110)$$

This can be solved for  $\theta_0$ :

$$\begin{aligned}
\Theta_0 = & \left[ \frac{6C_T}{Ta} - \frac{3}{4} \mu^2 b_2 (1-l_1) - \frac{3}{4} \mu^2 \Theta_1 (1-l_1^2) - \frac{3}{4} \Theta_1 (1-l_1^4) \right] \\
& + \frac{3}{4} \mu a_1 (1-l_1^2) - \frac{3}{4} \varepsilon \mu a_1 (3-2l_1-l_1^2) \\
& + 3 \int_{l_1}^{1.0} \left( \frac{\mu}{2} \lambda_{1s} + \eta \lambda_0 \right) d\eta \Bigg] / \left( 1-l_1^3 + \frac{3}{2} \mu^2 \right) \quad (3.111)
\end{aligned}$$

In Eq. 3.93, there are five different types of terms: those containing no trigonometric functions of  $\psi$  and those containing either  $\sin n\psi$  or  $\cos n\psi$  for  $n = 1$  or  $n = 2$ , since all terms with  $n > 2$  have been dropped. Thus, Eq. 3.93 can be written:

$$F_0 + F_{1c} \cos \psi + F_{1s} \sin \psi + F_{2c} \cos 2\psi + F_{2s} \sin 2\psi = 0 \quad (3.112)$$

Since Eq. 3.112 must be satisfied for all  $\psi$  between 0 and  $2\pi$ , the individual factors  $F$  must each be zero. This gives five equations for the five harmonic components of  $\beta$ . Solving these equations:

$$\begin{aligned}
a_0 = & \left( \frac{a}{2\pi} \right) \left( \frac{LN}{2} \right) \left[ \left( \frac{\mu^2}{2} I_0 + I_2 \right) \Theta_0 + \left( \frac{\mu^2}{2} I_1 + I_3 \right) \Theta_1 \right. \\
& + \left( \frac{\varepsilon}{2} I_0 + \frac{\varepsilon}{2} I_1 - I_1 \right) \mu a_1 + \frac{\mu^2}{4} I_0 b_2 \\
& \left. - \int_{l_1}^{1.0} (\eta - \varepsilon) \left( \frac{\mu}{2} \lambda_{1s} + \eta \lambda_0 \right) d\eta \right] \quad (3.113)
\end{aligned}$$

$$a_1 = \left\{ 8\mu I_1 \theta_0 + 8\mu I_2 \theta_1 + \left[ 4\varepsilon \mu I_0 - 2(1+\varepsilon)\mu I_1 \right] b_2 + 4 \int_{\lambda_1}^{1.0} (\eta - \varepsilon) \left( \frac{\mu}{2} \lambda_{2c} - \mu \lambda_0 - \eta \lambda_{1s} \right) d\eta \right\} / (3\mu^2 I_0 + 4I_2 - 4\varepsilon I_1) \quad (3.114)$$

$$b_1 = \left\{ 4\mu I_1 a_0 + \left[ 2(1+\varepsilon)\mu I_1 - 4\varepsilon \mu I_0 \right] a_2 + 4 \int_{\lambda_1}^{1.0} (\eta - \varepsilon) \left( \frac{\mu}{2} \lambda_{1s} + \eta \lambda_{1c} \right) d\eta \right\} / (\mu^2 I_0 + 4I_2 - 4\varepsilon I_1) \quad (3.115)$$

$$a_2 = \left( \frac{a}{2\pi} \right) \left( \frac{F}{3} \right) \left( \frac{LN}{2} \right) \left\{ -\frac{\mu^2}{2} I_0 \theta_0 - \frac{\mu^2}{2} I_1 \theta_1 + \left[ \left( \frac{2-\varepsilon}{2} \right) \mu I_1 - \frac{\varepsilon \mu}{2} I_0 \right] a_1 + (2I_2 - 2\varepsilon I_1) b_2 + \int_{\lambda_1}^{1.0} (\eta - \varepsilon) \left( \frac{\mu}{2} \lambda_{1s} - \frac{\mu}{2} \lambda_{3s} - \eta \lambda_{2c} \right) d\eta \right\} \quad (3.116)$$

$$b_2 = \left( \frac{a}{2\pi} \right) \left( \frac{F}{3} \right) \left( \frac{LN}{2} \right) \left\{ -\frac{\mu^2}{2} I_0 a_0 + \left[ \left( \frac{2-\varepsilon}{2} \right) \mu I_1 - \frac{\varepsilon \mu}{2} I_0 \right] b_1 + (2\varepsilon I_1 - 2I_2) a_2 - \int_{\lambda_1}^{1.0} (\eta - \varepsilon) \left( \frac{\mu}{2} \lambda_{1c} - \frac{\mu}{2} \lambda_{3c} + \eta \lambda_{2s} \right) d\eta \right\} \quad (3.117)$$

where the integrals  $I$  are defined:

$$I_0 = \int_{\lambda_1}^{1.0} (\eta - \varepsilon) d\eta = \frac{1}{2} [1 - \lambda_1^2 - 2\varepsilon(1 - \lambda_1)] \quad (3.118)$$

$$I_1 = \int_{\lambda_1}^{1.0} \eta(\eta - \varepsilon) d\eta = \frac{1}{3} [1 - \lambda_1^3 - \frac{3\varepsilon}{2}(1 - \lambda_1^2)] \quad (3.119)$$

$$I_2 = \int_{\lambda_1}^{1.0} \eta^2(\eta - \varepsilon) d\eta = \frac{1}{4} [1 - \lambda_1^4 - \frac{4\varepsilon}{3}(1 - \lambda_1^3)] \quad (3.120)$$

$$I_3 = \int_{\lambda_1}^{1.0} \eta^3(\eta - \varepsilon) d\eta = \frac{1}{5} [1 - \lambda_1^5 - \frac{5\varepsilon}{4}(1 - \lambda_1^4)] \quad (3.121)$$

These six equations (3.111 plus 3.113-3.117) are coupled. To eliminate the  $a_1 - \theta_0$  coupling, substitute Eq. 3.114 into Eq. 3.111 and solve for  $\theta_0$ :

$$\begin{aligned} \theta_0 = & \left\{ \frac{6C_T}{\sigma a} - \frac{3\mu^2}{4} (1 - \lambda_1) b_2 - \frac{3\mu^2}{4} (2 - \lambda_1^2 - \lambda_1^4) \theta_1 \right. \\ & + 3 \int_{\lambda_1}^{1.0} \left( \frac{\mu}{2} \lambda_{13} + \eta \lambda_0 \right) d\eta + \frac{3\mu}{4} \left[ \frac{(2 - \varepsilon)(1 - \lambda_1^2) - 2\varepsilon(1 - \lambda_1)}{3\mu^2 I_0 + 4I_2 - 4\varepsilon I_1} \right] \\ & \left. \left[ 2(2\varepsilon I_0 - \varepsilon I_1 - I_1) \mu b_2 + 8\mu \theta_1 I_2 + \int_{\lambda_1}^{1.0} (\eta - \varepsilon) \left( \frac{\mu}{2} \lambda_{12} - \mu \lambda_0 - \eta \lambda_{13} \right) d\eta \right] \right\} \\ & / \left\{ \left( 1 + \frac{3\mu^2}{2} - \lambda_1^3 \right) - 6\mu^2 I_1 \left[ \frac{(2 - \varepsilon)(1 - \lambda_1^2) - 2\varepsilon(1 - \lambda_1)}{3\mu^2 I_0 + 4I_2 - 4\varepsilon I_1} \right] \right\} \end{aligned}$$

(3.122)

To eliminate  $a_2 - b_2$  coupling, substitute Eq. 3.117 into Eq. 3.116 and solve for  $a_2$ :

$$a_2 = \left( \frac{a}{2\pi} \right) \left( \frac{F}{3} \right) \left( \frac{LN}{2} \right) \left\{ \left( -\frac{\mu^2}{2} I_0 \theta_0 - \frac{\mu^2}{2} I_1 \theta_1 - \frac{\mu}{2} \left[ \varepsilon I_0 - (2-\varepsilon) I_1 \right] a_1 \right. \right. \\ \left. + \int_{\lambda_1}^{1.0} (\eta - \varepsilon) \left( \frac{\mu}{2} \lambda_{1s} - \frac{\mu}{2} \lambda_{3s} - \eta \lambda_{2c} \right) d\eta + \left( \frac{a}{2\pi} \right) \left( \frac{F}{3} \right) \left( \frac{LN}{2} \right) (I_2 - \varepsilon I_1) \right. \\ \left. \left[ -\frac{\mu^2}{2} I_0 a_0 - \frac{\mu}{2} (\varepsilon I_0 - 2I_1 + \varepsilon I_1) b_1 - \int_{\lambda_1}^{1.0} (\eta - \varepsilon) \left( \frac{\mu}{2} \lambda_{1c} - \frac{\mu}{2} \lambda_{3c} + \eta \lambda_{2s} \right) d\eta \right] \right\} \\ \left/ \left[ 1 + F^2 \left( \frac{a}{2\pi} \right)^2 \left( \frac{LN}{3} \right)^2 (I_2 - \varepsilon I_1)^2 \right] \right.$$

(3.123)

To save ourselves from further algebra and longer equations, note that  $a_2$  and  $b_2$  are normally at least an order of magnitude smaller than  $\theta_0$ ,  $a_0$ ,  $a_1$ , and  $b_1$ . This allows the use of the following computation scheme:

- 1) Assume  $a_2 = b_2 = 0$
  - 2) Compute  $\theta_0$  from Eq. 3.122
  - 3) Compute  $a_1$  from Eq. 3.114
  - 4) Compute  $a_0$  from Eq. 3.113
  - 5) Compute  $b_1$  from Eq. 3.115
  - 6) Compute  $a_2$  from Eq. 3.123
  - 7) Compute  $b_2$  from Eq. 3.117
  - 8) Repeat steps 2 through 7, using new values of  $a_2$  and  $b_2$ .
- Normally, one iteration is adequate.

In the equations above all integrals over  $\eta$  which contain harmonics of  $\lambda(\eta, \psi)$  are not performed since these harmonics are functions of  $\eta$ . The program LDS-73 performs these integrations numerically.

The coning angle  $a_o$  is an input to LDS-73 which must be computed by hand. A simplified expression for  $a_o$  is, therefore, developed, assuming:  $\epsilon = 0$ ,  $F = 1.0$ ,  $\lambda(\eta, \psi) = \lambda_o$ , and that  $\mu^3$  can be neglected compared to one.

$$a_o = \left(\frac{a}{2\pi}\right) \left(\frac{LN}{4}\right) \left[ \left(1 - \frac{\mu^2}{18}\right) \frac{3C_T}{\pi a} + \left(1 - \frac{5\mu^2}{2}\right) \frac{\lambda}{12} + \left(1 + \frac{5\mu^2}{6}\right) \frac{\theta_1}{40} \right] \quad (3.124)$$

This can be further simplified to:

$$a_o = \frac{3}{4} \left(\frac{LN}{2\pi}\right) \left(\frac{C_T}{\pi}\right) \quad (3.3)$$

with some sacrifice in accuracy.

It is often useful to isolate the contributions of  $C_T$ ,  $\theta_1$ , the various harmonics of  $\lambda(\eta, \psi)$ ,  $a_2$ , and  $b_2$  to  $\theta_o$ ,  $a_o$ ,  $a_1$ , and  $b_1$ . This is done in LDS-73 by appropriate bookkeeping when this harmonic solution was programmed.

The harmonic solution given above neglects compressibility. The important compressibility effect on blade motion is the increase of the lift-curve slope  $\partial C_L / \partial a$  with Mach number. An average correction factor for this (GMA) is developed in Subsection 3.3.2 (Eq. 3.161). This can be applied to the harmonic solution by replacing the lift-curve slope  $a$  with  $(a/GMA)$  wherever  $a$  appears.

### 3.3.2 Numerical Solution

The fundamental assumption of the numerical solution is that the blade motion consists of rigid body flapping and first mode flapwise blade bending. Given assumed mode shapes, this leads to two linearized, coupled equations for the amplitudes as a function of azimuth. These equations are solved numerically.

Since all blade motion is assumed to take place outboard of the flapping hinge, the length of the blade outboard of the flapping hinge  $L = (1 - \epsilon)R$  is often used to normalize variables instead of  $R$ . Variables normalized by  $L$  instead of  $R$  will be identified by a bar above them. Thus the normalized radial coordinate becomes:

$$\bar{\eta} = (\eta - \epsilon) / (1 - \epsilon) \quad (3.125)$$

The vertical displacement of point  $P_{\bar{\eta}}$  on the  $\eta$  blade relative to the no feathering plane (NFP) is  $\bar{z}(\bar{\eta}, \psi)$  (normalized by  $L$ ). This  $\bar{z}(\bar{\eta}, \psi)$  can be written in terms of two normal modes:

$$\bar{z}(\bar{\eta}, \psi) = \gamma_1(\bar{\eta}) q_1(\psi) + \gamma_2(\bar{\eta}) q_2(\psi) \quad (3.126)$$

The first mode is rigid body flapping. Therefore:

$$\gamma_1(\bar{\eta}) = \bar{\eta} \quad (3.127)$$

$$q_1(\psi) = \beta(\psi) \quad (3.128)$$

The second mode is the first flapwise mode of blade bending. The choice of a mode shape  $\gamma_2(\bar{\eta})$  is discussed in Appendix G. The mode shape normally used is:

$$\gamma_2(\bar{\eta}) = 4\bar{\eta}^2 - 3\bar{\eta} \quad (3.129)$$

based on the assumption of a uniform radial blade mass distribution  $m(\bar{\eta})$  (slugs/ft) outboard of the flapping hinge.

The amplitude of the blade motion is assumed to be small enough that all terms in the blade-motion equations which are nonlinear in  $q_1$  and  $q_2$  can be neglected. Provision is made for a torsional spring of stiffness  $k$  (ft-lb/radian) about the flapping hinge. This spring can be used, together with flapping hinge offset, to simulate a hingeless, cantilever rotor. The resulting linearized equations of blade motion are:

$$M_5 \ddot{q}_1 + M_1 \dot{q}_1 + M_2 \dot{q}_2 + K \left[ q_1 + q_2 \left( \frac{dY_2}{d\bar{\eta}} \right)_{\bar{\eta}=0} \right] = Q_1 \quad (3.130)$$

$$M_6 \ddot{q}_2 + M_2 \dot{q}_1 + M_4 \dot{q}_2 + M_7 \dot{q}_2 + K \left( \frac{dY_2}{d\bar{\eta}} \right)_{\bar{\eta}=0} \left[ q_1 + q_2 \left( \frac{dY_2}{d\bar{\eta}} \right)_{\bar{\eta}=0} \right] = Q_2 \quad (3.131)$$

where the M's are various mass integrals, K is a normalized k,  $Q_1$  and  $Q_2$  are generalized forces due to airloads,  $EI(\bar{\eta})$  is the radial distribution of flapwise stiffness (lb-ft<sup>2</sup>) of the rotor blade, and the dot notation represents differentiation with respect to azimuth angle ( $\psi$ ).

$$M_1 = \frac{2}{\rho a c R} \int_0^1 \bar{\eta} (\bar{\epsilon} + \bar{\eta}) m(\bar{\eta}) d\bar{\eta} \quad (3.132)$$

$$M_2 = \frac{2}{\rho a c R} \int_0^1 \bar{\epsilon} m(\bar{\eta}) d\bar{\eta} \quad (3.133)$$

$$M_4 = \frac{2}{\rho a c R} \int_0^1 (\bar{\epsilon} + \bar{\eta}) \left[ \int_0^{\bar{\eta}} \left( \frac{dY_2}{d\xi} \right)^2 d\xi \right] m(\bar{\eta}) d\bar{\eta} \quad (3.134)$$

$$M_5 = \frac{2}{\rho a c R} \int_0^1 \bar{\eta}^2 m(\bar{\eta}) d\bar{\eta} \quad (3.135)$$

$$M_6 = \frac{2}{\rho a c R} \int_0^1 Y_2^2 m(\bar{\eta}) d\bar{\eta} \quad (3.136)$$

$$M_7 = \frac{2}{\rho a c R \Omega^2 L^4} \int_0^1 \left( \frac{d^2 Y_2}{d\bar{\eta}^2} \right)^2 EI(\bar{\eta}) d\bar{\eta} \quad (3.137)$$

$$K = 2k / \rho a c R \Omega^2 L^3 \quad (3.138)$$

$$Q_1 = (1-\varepsilon)^{-2} \int_{\lambda_1}^{1.0} \bar{\eta} \left[ \frac{2L(\eta, \psi)}{\rho_{ac} (\Omega R)^2} \right] d\eta \quad (3.139)$$

$$Q_2 = (1-\varepsilon)^{-2} \int_{\lambda_1}^1 \gamma_2 \left[ \frac{2L(\eta, \psi)}{\rho_{ac} (\Omega R)^2} \right] d\eta \quad (3.140)$$

The equations for the M's can be simplified for the case of a uniform blade mass distribution [ $m(\bar{\eta}) = \text{constant}$ ]. For typical high aspect ratio rotor blades, this implies a flapwise moment of inertia about the flapping hinge of:

$$I_b = \frac{m(\bar{\eta}) L^3}{3} \quad (3.141)$$

From the definition of LN (Eq. 3.90),

$$LN = (1-\varepsilon)^{-3} \frac{6\pi\rho c R}{m(\bar{\eta})} \quad (3.142)$$

Assuming  $\gamma_2(\bar{\eta})$  given by Eq. 3.129, the M's can now be written in terms of LN for constant  $m(\bar{\eta})$ :

$$M_1 = \frac{2\pi}{LN_a} (1-\varepsilon)^{-3} \left[ 2 + \left( \frac{3\varepsilon}{1-\varepsilon} \right) \right] \quad (3.143)$$

$$M_2 = \frac{2\pi}{LN_a} (1-\varepsilon)^{-3} \left[ \frac{-\varepsilon}{1-\varepsilon} \right] \quad (3.144)$$

$$M_4 = \frac{2\pi}{LN_a} (1-\varepsilon)^{-3} \left[ \frac{38}{5} + 11 \left( \frac{\varepsilon}{1-\varepsilon} \right) \right] \quad (3.145)$$

$$M_5 = \frac{2\pi}{LN_a} (1-\varepsilon)^{-3} [2] \quad (3.146)$$

$$M_6 = \frac{2\pi}{LN_a} (1-\varepsilon)^{-3} \left[ \frac{6}{5} \right] \quad (3.147)$$

Assuming a uniform stiffness distribution  $[EI(\bar{\eta}) = EI = \text{constant}]$ :

$$M_7 = \frac{128 (1-\varepsilon)^{-4}}{\rho a c R \Omega^2 R^4} [EI] \quad (3.148)$$

The normalized  $k$  can be written in terms of  $R$  and  $\varepsilon$  instead of  $L$ :

$$K = \frac{2 k (1-\varepsilon)^{-3}}{\rho a c R \Omega^2 R^3} \quad (3.149)$$

Now the equations of blade motion can be simplified for this special case:

$$M_5 \ddot{q}_1 + M_1 \dot{q}_1 + M_2 \dot{q}_2 + K [q_1 - 3 q_2] = Q_1 \quad (3.150)$$

$$M_6 \ddot{q}_2 + M_2 \dot{q}_1 + (M_4 + M_7) \dot{q}_2 - 3K [q_1 - 3 q_2] = Q_2 \quad (3.151)$$

These are the equations used in LDS-73, together with the  $\gamma_2(\bar{\eta})$  given by Eq. 3.129.

An expression for  $L(\eta, \psi)$  can be obtained by combining Eq. 3.89 and Eq. 3.94:

$$L(\eta, \psi) = \frac{1}{2} \rho a c (\Omega R)^2 \left[ F U_T^2 \alpha(\eta, \psi) + (1-F) \frac{2 C_T}{\sigma a} \right] \quad (3.152)$$

The tangential airspeed  $U_T$  is computed from either Eq. 3.84, if tangential induced velocities are included, or Eq. 3.98, if they are neglected. The perpendicular airspeed  $U_p$  is computed assuming that  $q_1$  and  $q_2$  are small angles:

$$U_p(\eta, \psi) = \lambda(\eta, \psi) + \mu a_1 + \left[ q_1 + q_2 \left( \frac{d\gamma_2}{d\bar{\eta}} \right) \right] \mu \cos \psi \quad (3.153)$$

$$+ \bar{\eta} \dot{q}_1 + \gamma_2(\bar{\eta}) \dot{q}_2$$

The general expression for angle of attack is:

$$\alpha(\eta, \psi) = \theta(\eta) - \tan^{-1} (U_p / U_T) \quad (3.95)$$

For part of the numerical solution, a small angle version of this expression is used:

$$\alpha(\eta, \psi) = \theta(\eta) - u_p / u_T \quad (3.154)$$

These expressions for  $\alpha(\eta, \psi)$  do not apply in the reverse flow region ( $u_T < 0$ ). Taking only the principal value of  $\tan^{-1}(u_p/u_T)$ :

$$\alpha(\eta, \psi) = \begin{cases} \theta(\eta) - \tan^{-1}(u_p/u_T) & , u_T > 0 \\ -\theta(\eta) + \tan^{-1}(u_p/u_T) & , u_T < 0 \end{cases} \quad (3.155)$$

For the small angle version:

$$u_T^2 \alpha(\eta, \psi) = |u_T| [u_T \theta(\eta) - u_p] \quad (3.156)$$

which applies for all  $u_T$ .

Now  $Q_1$  and  $Q_2$  can be written using Eq. 152 and Eq. 3.156):

$$Q_1 = (1-\varepsilon)^{-2} \int_{\lambda_1}^1 \bar{\eta} \left\{ F |u_T| [u_T \theta(\eta) - u_p] + (1-F) \frac{2 C_T}{\sigma a} \right\} d\eta \quad (3.157)$$

$$Q_2 = (1-\varepsilon)^{-2} \int_{\lambda_1}^1 \gamma_2 \left\{ F |u_T| [u_T \theta(\eta) - u_p] + (1-F) \frac{2 C_T}{\sigma a} \right\} d\eta \quad (3.158)$$

These equations for  $Q_1$  and  $Q_2$  assume that the lift-curve slope is a constant. It is desirable to modify this assumption to include stall and compressibility effects. Stall will be included later. The compressibility correction is:

$$\frac{\partial C_L}{\partial \alpha} = \frac{a}{GM(\eta, \psi)} \quad (3.159)$$

$$GM(\eta, \psi) = M_{ax.} \left\{ \frac{0.6}{\sqrt{1 - [M(\eta, \psi)]^2}} \right\} \quad (3.160)$$

where  $M(\eta, \psi)$  is the local Mach number:

$$M(\eta, \psi) = \Omega R U_T(\eta, \psi) / 1100. \quad (3.161)$$

An average compressibility correction is also defined:

$$GMA = M_{ax.} \left\{ \frac{0.6}{\sqrt{1 - [0.75 \Omega R / 1100]^2}} \right\} \quad (3.162)$$

The average correction GMA can be applied to the lift-curve slope  $a$  used in the harmonic solution. It is not needed for the numerical solution where  $GM(\eta, \psi)$  is used.

To understand the use of  $GM(\eta, \psi)$ , recall that  $a$  is a constant input,  $\partial C_L / \partial \alpha$ , and that the actual  $\partial C_L / \partial \alpha$  is obtained by multiplying  $a$  by an appropriate factor. The equations of blade motion are normalized by a factor which includes  $a$  but not any factors which might multiply  $a$ . Thus, any correction factors for  $a$  multiply the angle of attack  $\alpha(\eta, \psi)$  in the equations of motion, not  $a$ . This implies that:

$$Q_1 = (1 - \varepsilon) \int_{\lambda_1}^1 \bar{\gamma} \left\{ \frac{F |U_T|}{GM(\eta, \psi)} [U_T \theta(\eta) - U_P] + (1 - F) \frac{2 C_T}{\sigma a} \right\} d\eta \quad (3.163)$$

$$Q_2 = (1 - \varepsilon) \int_{\lambda_1}^1 \gamma_2 \left\{ \frac{F |U_T|}{GM(\eta, \psi)} [U_T \theta(\eta) - U_P] + (1 - F) \frac{2 C_T}{\sigma a} \right\} d\eta \quad (3.164)$$

The  $U_P$  terms in  $Q_1$  and  $Q_2$  contain the dependent variables  $q_1$  and  $q_2$ . To isolate this dependence write:

$$Q_1 = C_1 - C_2 \dot{q}_1 - C_3 \dot{q}_2 - C_4 q_1 - C_5 q_2 \quad (3.165)$$

$$Q_2 = C_6 - C_3 \dot{q}_1 - C_8 \dot{q}_2 - C_7 q_1 - C_{10} q_2 \quad (3.166)$$

which implies that:

$$C_1 = (1-\varepsilon)^{-2} \int_{\lambda_1}^1 \bar{\eta} \left\{ \frac{F|u_T|}{GM(\eta, \psi)} [u_T \theta(\eta) - \lambda(\eta, \psi) - \mu a_1] - (1-F) \frac{2C_T}{\sigma a} \right\} d\eta \quad (3.167)$$

$$C_6 = (1-\varepsilon)^{-2} \int_{\lambda_1}^1 \gamma_2 \left\{ \frac{F|u_T|}{GM(\eta, \psi)} [u_T \theta(\eta) - \lambda(\eta, \psi) - \mu a_1] - (1-F) \frac{2C_T}{\sigma a} \right\} d\eta \quad (3.168)$$

$$C_2 = (1-\varepsilon)^{-2} \int_{\lambda_1}^1 \left[ \frac{F|u_T|}{GM(\eta, \psi)} \right] [\bar{\eta}]^2 d\eta \quad (3.169)$$

$$C_3 = (1-\varepsilon)^{-2} \int_{\lambda_1}^1 \left[ \frac{F|u_T|}{GM(\eta, \psi)} \right] \bar{\eta} \gamma_2 d\eta \quad (3.170)$$

$$C_8 = (1-\varepsilon)^{-2} \int_{\lambda_1}^1 \left[ \frac{F|u_T|}{GM(\eta, \psi)} \right] [\gamma_2]^2 d\eta \quad (3.171)$$

$$C_4 = (1-\varepsilon)^{-2} \int_{\lambda_1}^1 \left[ \frac{F|u_T| \mu \cos \psi}{GM(\eta, \psi)} \right] \bar{\eta} d\eta \quad (3.172)$$

$$C_7 = (1-\varepsilon)^{-2} \int_{\lambda_1}^1 \left[ \frac{F|u_T| \mu \cos \psi}{GM(\eta, \psi)} \right] \gamma_2 d\eta \quad (3.173)$$

$$C_5 = (1-\varepsilon)^{-2} \int_{\lambda_1}^1 \left[ \frac{F|u_T| \mu \cos \psi}{GM(\eta, \psi)} \right] \bar{\eta} \left[ \frac{d\gamma_2}{d\bar{\eta}} \right] d\eta \quad (3.174)$$

$$C_{10} = (1-\varepsilon)^{-2} \int_{\lambda_1}^1 \left[ \frac{F |U_T| \mu \cos \psi}{GM(\eta, \psi)} \right] \gamma_2 \left[ \frac{d\gamma_2}{d\eta} \right] d\eta \quad (3.175)$$

For a given  $\gamma_2(\bar{\eta})$ , such as Eq. 129, all of the C's, except  $C_1$  and  $C_6$  can be integrated in closed form, if  $q_T(\eta, \psi)$ , the induced contribution to  $U_T$ , is neglected. This is not done in LDS-73 where the option to include  $q_T(\eta, \psi)$  has been retained by using numerical integration.

Dynamic stall effects will be included in the final airloads computation (Subsection 3.4.2), but they are only very simply represented in the numerical solution for blade motion. This is because the computation of dynamic stall effects in the final airloads solution shows that they are small for the low advance ratio cases considered here. Should it become necessary, dynamic stall could be included in the numerical solution, but this would require a major revision to accurately predict  $\dot{\alpha} = \partial\alpha/\partial\psi$ .

For the numerical solution in LDS-73, dynamic stall is simply represented by raising the static stall angle of attack ( $\alpha_s$ ) to  $20^\circ$ . The  $C_L$  vs  $\alpha$  curve used is shown in Fig. 22, where  $\partial C_L/\partial\alpha$  is obtained from Eq. 3.159. To apply this  $\alpha(\eta, \psi)$  is computed using Eq. 3.155 just before the C's are computed. If  $|\alpha(\eta, \psi)| < \alpha_s$ , then the C's are computed normally (Eq. 3.167 to Eq. 3.175). If  $|\alpha(\eta, \psi)| > \alpha_s$ , then all of the coefficients for  $q_1, q_2, \dot{q}_1, \dot{q}_2$  ( $C_2, C_3, C_4, C_5, C_8, C_9, C_{10}$ ) are set equal to zero, since  $\partial C_L/\partial\alpha = 0$ . The terms which do not depend on blade motion become:

$$C_1 = (1-\varepsilon)^{-2} \int_{\lambda_1}^{1.0} \bar{\eta} \left[ \frac{F U_T^2 \alpha(\eta, \psi)}{GM(\eta, \psi) |\alpha(\eta, \psi)|} \alpha_s - (1-F) \frac{2C_T}{\sigma a} \right] d\eta \quad (3.176)$$

$$C_2 = (1-\varepsilon)^{-2} \int_{\lambda_1}^{1.0} \gamma_2(\bar{\eta}) \left[ \frac{F U_T^2 \alpha(\eta, \psi)}{GM(\eta, \psi) |\alpha(\eta, \psi)|} \alpha_s - (1-F) \frac{2C_T}{\sigma a} \right] d\eta \quad (3.177)$$

Now the equations of blade motion (Eq. 3.150, 3.151) can be rewritten using these coefficients  $C_1 - C_{10}$ .

$$M_5 \ddot{q}_1 + C_2 \dot{q}_1 + C_3 \dot{q}_2 + (M_1 + C_4 + K) q_1 + (M_2 + C_5 - 3K) q_2 = C_1 \quad (3.178)$$

$$M_6 \ddot{q}_2 + C_3 \dot{q}_1 + C_8 \dot{q}_2 + (M_2 + C_9 - 3K) q_1 + (M_4 + M_7 + C_{10} + 9K) q_2 = C_6 \quad (3.179)$$

In review, observe that all of the blade motion ( $q_1, q_2$ ) dependence in the equations of motion has been made explicit in Eqs. 178 and 3.179 with the exception of that contained in  $\partial C_L / \partial \alpha$ . Recall that when these equations were normalized, they were divided by  $a$ , where  $a$  is an input, constant  $\partial C_L / \partial \alpha$ . The actual  $\partial C_L / \partial \alpha$  is multiplied by appropriate correction factors for compressibility and stall. These lift-curve slope correction factors multiply the coefficients  $C_1 - C_{10}$ . The compressibility-correction factor is  $[1.0/GM(\eta, \psi)]$ , which is independent of blade motion. Stall is a function of angle of attack  $\alpha$ , which is in turn a function of blade motion. Thus, the stall-correction factor for  $\partial C_L / \partial \alpha$  is a function of blade motion. This dependence of  $\partial C_L / \partial \alpha$  on blade motion makes the blade-motion equations nonlinear. To avoid this nonlinearity, a very simple  $C_L$  vs  $\alpha$  curve is used (Fig. 22). Using this curve,  $\partial C_L / \partial \alpha$  is either a constant, for  $\alpha$  below stall, or  $\partial C_L / \partial \alpha$  is zero, for  $\alpha$  above stall. The choice between the two possible values of  $\partial C_L / \partial \alpha$  is made at each step in the iterative, numerical blade-motion solution, by computing  $\alpha(\eta, \psi)$  using the best available estimate of the blade motion.

A finite difference solution technique for equations similar to Eqs. 3.178 and 3.179 is described on pages 668 to 672 of Bisplinghoff, Ashley, and Halfman [56]. The basis of this technique is a set of formulas for the first and second derivatives of blade motion  $q(\psi)$  with respect to azimuth angle  $\psi$  in terms of the blade motion at the last four azimuth angle steps:

$$\dot{q}(\psi) = \frac{11q(\psi) - 18q(\psi - \Delta\psi) + 9q(\psi - 2\Delta\psi) - 2q(\psi - 3\Delta\psi)}{6\Delta\psi} \quad (3.180)$$

$$\ddot{q}(\psi) = \frac{2q(\psi) - 5q(\psi - \Delta\psi) + 4q(\psi - 2\Delta\psi) - q(\psi - 3\Delta\psi)}{(\Delta\psi)^2} \quad (3.181)$$

These formulas can be used to compute  $\dot{q}_1(\psi)$ ,  $\dot{q}_2(\psi)$ ,  $\ddot{q}_1(\psi)$ , and  $\ddot{q}_2(\psi)$  and the resulting expressions can be substituted into Eqs. 3.178 and 3.179. This leads to the following equations for  $q_1(\psi)$  and  $q_2(\psi)$ :

$$a_{11} q_1(\psi) + a_{12} q_2(\psi) = y_1 \quad (3.182)$$

$$a_{21} q_1(\psi) + a_{22} q_2(\psi) = y_2 \quad (3.183)$$

where:

$$a_{11} = \frac{2M_5}{(\Delta\psi)^2} + \frac{11C_2}{6\Delta\psi} + M_1 + K + C_4 \quad (3.184)$$

$$a_{12} = \frac{11C_3}{6\Delta\psi} + M_2 + C_5 - 3K \quad (3.185)$$

$$a_{21} = \frac{11C_3}{6\Delta\psi} + M_2 + C_9 - 3K \quad (3.186)$$

$$a_{22} = \frac{2M_6}{(\Delta\psi)^2} + \frac{11C_8}{6\Delta\psi} + M_4 + M_7 + C_{10} + 9K \quad (3.187)$$

$$\begin{aligned}
y_1 = & C_1 + \left[ \frac{5M_5}{(\Delta\psi)^2} + \frac{3C_2}{\Delta\psi} \right] q_1(\psi - \Delta\psi) - \left[ \frac{4M_5}{(\Delta\psi)^2} + \frac{3C_2}{2\Delta\psi} \right] q_1(\psi - 2\Delta\psi) \\
& + \left[ \frac{M_5}{(\Delta\psi)^2} + \frac{C_2}{3\Delta\psi} \right] q_1(\psi - 3\Delta\psi) + \frac{3C_3}{\Delta\psi} q_2(\psi - \Delta\psi) \\
& - \frac{3C_3}{2\Delta\psi} q_2(\psi - 2\Delta\psi) + \frac{C_3}{3\Delta\psi} q_2(\psi - 3\Delta\psi)
\end{aligned} \tag{3.188}$$

$$\begin{aligned}
y_2 = & C_6 + \left[ \frac{5M_6}{(\Delta\psi)^2} + \frac{3C_8}{\Delta\psi} \right] q_2(\psi - \Delta\psi) - \left[ \frac{4M_6}{(\Delta\psi)^2} + \frac{3C_8}{2\Delta\psi} \right] q_2(\psi - 2\Delta\psi) \\
& + \left[ \frac{M_6}{(\Delta\psi)^2} + \frac{C_8}{3\Delta\psi} \right] q_2(\psi - 3\Delta\psi) + \frac{3C_3}{\Delta\psi} q_1(\psi - \Delta\psi) \\
& - \frac{3C_3}{2\Delta\psi} q_1(\psi - 2\Delta\psi) + \frac{C_3}{3\Delta\psi} q_1(\psi - 3\Delta\psi)
\end{aligned} \tag{2.189}$$

Solving these equations for  $q_1(\psi)$  and  $q_2(\psi)$ :

$$q_1(\psi) = \frac{a_{22} y_1 - a_{12} y_2}{a_{11} a_{22} - a_{12} a_{21}} \tag{3.190}$$

$$q_2(\psi) = \frac{a_{11} y_2 - a_{21} y_1}{a_{11} a_{22} - a_{12} a_{21}} \tag{3.191}$$

The results of the harmonic solution for blade motion are used to initialize the numerical solution. Thus the initial values for blade motion are:

$$q_1(\psi) = a_0 - a_1 \cos \psi - b_1 \sin \psi - a_2 \cos 2\psi - b_2 \sin 2\psi \quad (3.192)$$

$$\dot{q}_1(\psi) = a_1 \sin \psi - b_1 \cos \psi + 2a_2 \sin 2\psi - 2b_2 \cos 2\psi \quad (3.193)$$

$$q_2(\psi) = 0.0 \quad (3.194)$$

$$\dot{q}_2(\psi) = 0.0 \quad (3.195)$$

The harmonic solution result for  $\theta_0$  is also used as an initial value for the numerical solution. The initial azimuthal step size  $\Delta\psi$  used in the numerical solution is the same as the  $\Delta\psi$  used elsewhere in LDS-73. The solution proceeds as follows:

- 1) Initialize the blade pitch using  $\theta_0$  from the harmonic solution and an input twist  $\theta_T(\eta)$

$$\theta(\eta) = \theta_0 + \theta_T(\eta) \quad (3.196)$$

- 2) Initialize  $q_1, \dot{q}_1, q_2, \dot{q}_2$  for  $\psi = 0, \Delta\psi, 2\Delta\psi, \dots, 2\pi$  using Eqs. 3.192 through 3.195.
- 3) Start loop where  $\psi$  runs from 0 to  $2\pi$  in steps of  $\Delta\psi$
- 4) Compute  $\alpha(\eta, \psi)$  using Eq. 3.155.

- 5) Compute  $C_1 - C_{10}$  using either Eqs. 3.167 through 3.175 or Eqs. 3.176 through 3.177 depending on the value of  $\alpha(\eta, \psi)$
- 6) Compute new values for  $q_1(\psi)$  and  $q_2(\psi)$  using Eqs. 3.190 through 3.191.
- 7) Compute new values of  $\dot{q}_1(\psi)$  and  $\dot{q}_2(\psi)$  using  $q_1(\psi)$  and  $q_2(\psi)$  from step (6) in Eq. 3.180.
- 8) End of  $\psi$  loop: either increment  $\psi$  by  $\Delta\psi$  and go to step (4) or, if  $\psi = 2\pi$ , go to step (9)
- 9) Check for convergence. Require:

$$|q_1(0) - q_1(2\pi)| < EQ \quad (3.197)$$

$$|q_2(0) - q_2(2\pi)| < EQ \quad (3.198)$$

$$|\dot{q}_1(0) - \dot{q}_1(2\pi)| < EQ \quad (3.199)$$

$$|\dot{q}_2(0) - \dot{q}_2(2\pi)| < EQ \quad (3.200)$$

for convergence, where EQ is an input (normally  $EQ = 10^{-5}$ ). If converged, go to step (12), otherwise go to step (10).

- 10) If more than NQIM (input, normally NQIM = 25), iterations have been done, halve  $\Delta\psi$  and go back to step (2). Since  $\Delta\psi$  is now less than the value used by the rest of LDS-73, linear interpolation

is used for  $\lambda(\eta, \psi)$ . Halving  $\Delta\psi$  is only attempted NQCM (input, normally NQCM = 1) times.

- 11) If less than NQIM iterations have been done, harmonically analyze  $q_1(\psi)$  to obtain  $a_1$  which updates the value of  $\mu a_1$  used in computing  $\alpha(\eta, \psi)$ . Set  $q_1, q_2, \dot{q}_1, \dot{q}_2$  equal to the weighted average of their values from the last two iterations (WF = input weighting factor, normally WF = 0.5). Set:  $q_1(0) = q_1(2\pi), q_2(0) = q_2(2\pi), \dot{q}_1(0) = \dot{q}_1(2\pi)$ , and  $\dot{q}_2(0) = \dot{q}_2(2\pi)$  and go to step (3).

- 12) Compute  $C_T$  using  $\alpha(\eta, \psi)$  from step (5) in Eq. 3.94 (modified to include stall and compressibility effects)
- 13) Check for  $C_T$  convergence. Require

$$|C_T - C_{T_0}| < ECT \quad (3.201)$$

where  $C_{T_0}$  is the required  $C_T$ (input) and ECT is an input (normally  $ECT = 2 \times 10^{-5}$ ). If converged, the solution is complete. Otherwise change  $\theta_0$ :

$$\theta_0 = \theta_0 + (C_{T_0} - C_T) \frac{\partial \theta_0}{\partial C_T} \quad (3.202)$$

where  $\partial \theta_0 / \partial C_T$  is readily obtained by differentiating Eq. 3.122 with respect to  $C_T$ . Initialize  $\theta(\eta)$  using Eq. 3.196 and go to step (3).

### 3.4 Airloads and Performance

This subsection assumes that the downwash  $\lambda(\eta, \psi)$  and the blade motion are known. The task here is to compute rotor airloads and performance. The aerodynamic forces can be resolved in various ways. The aerodynamic forces computed here are: airloads (lift), drag, thrust, horizontal force, azimuthal force, and radial force. All of these are computed at each point  $P_\eta$  on the rotor and are output either in (lb/in) or, for the drag, in coefficient form. The total thrust, horizontal force and propulsive force for the entire rotor are computed as output in coefficient form. Torque coefficient is computed including a breakdown into parasite torque and induced torque. Finally, rotor equivalent lift to drag ratio (L/D) and total vehicle L/D are computed.

The angle of attack  $\alpha(\eta, \psi)$  is easily computed when downwash and blade motion are known. The important part of the computations in this subsection is therefore the  $C_L$  vs  $\alpha$  and  $C_D$  vs  $\alpha$  curves for a two-dimensional airfoil section. These curves are functions of Mach number and rate of change of angle of attack ( $\dot{\alpha} = \partial\alpha/\partial\psi$ ). For a production airloads computation, these airfoil section characteristics would normally be input data tables for each particular section used. For LDS-73, this is not done. Instead, a set of simplified functions is used to represent a generalized, cambered helicopter airfoil section. The representation used here is much more sophisticated than that used in the numerical blade motion solution, but it is not complicated enough to show the effects of different airfoil sections on rotor performance. It is anticipated that an industrial user of this work would modify this subsection to reflect his own airfoil section data.

#### 3.4.1 Angle of Attack

The first step is to compute the angle of attack  $\alpha(\eta, \psi)$  and its time rate of change  $\dot{\alpha}(\eta, \psi) = \partial\alpha/\partial\psi$ . The angle of attack  $\alpha(\eta, \psi)$  is computed using Eq. 3.155, repeated here:

$$\alpha(\eta, \psi) = \begin{cases} \theta(\eta) - \tan^{-1}(u_p/u_T) , & u_T > 0 \\ -\theta(\eta) + \tan^{-1}(u_p/u_T) , & u_T < 0 \end{cases} \quad (3.155)$$

The tangential airspeed  $U_T$  is computed using either Eq. 3.84, if tangential induced velocities are included, or Eq. 3.98, if they are neglected. The equation used for the perpendicular airspeed  $U_p$  depends on which blade motion solution was used. For the harmonic solution, Eq. 3.99 is used, where  $\beta$  and  $\dot{\beta}$  are obtained from Eq. 3.102 and Eq. 3.103, respectively. For the numerical solution, Eq. 3.152 is used.

The time rate of change of angle of attack is approximated by:

$$\dot{\alpha}(\eta, \psi) = [\alpha(\eta, \psi) - \alpha(\eta, \psi - \Delta\psi)] / \Delta\psi \quad (3.203)$$

#### 3.4.2 Airfoil Section Characteristics - Lift

The technique used here to represent radial flow and dynamic stall effects on lift is adapted from Harris [57]. This technique represents these effects by the use of an artificial  $\partial C_L / \partial \alpha$ . The original technique [57] is adaptable to any airfoil section, but the specialized version used here is intended to represent a typical, cambered helicopter airfoil section.

Define the chordwise and spanwise (radial) components of the total velocity in the TPP at point  $P_\eta$ . The chordwise component is:

$$V_{CH} = U_T(\eta, \psi) \quad (3.204)$$

where  $U_T$  comes from Eq. 3.84 or Eq. 3.98. The spanwise (radial) component is:

$$V_{sp} = \mu \cos \psi \quad (3.205)$$

The total (resultant) velocity is:

$$V_R = \sqrt{V_{CH}^2 + V_{sp}^2} \quad (3.206)$$

To avoid  $|\alpha(\eta, \psi)| > \pi/2$  define  $\alpha'$  such that  $|\alpha'| \leq \pi/2$ :

$$\alpha' = \begin{cases} \alpha(\eta, \psi) & , \alpha_m \leq \pi/2 \\ -\frac{\alpha(\eta, \psi)}{\alpha_m} [\pi - \alpha_m] & , \alpha_m > \pi/2 \end{cases} \quad (3.207)$$

where  $\alpha_m$  is:

$$\alpha_m = |\alpha(\eta, \psi)| \quad (3.208)$$

If  $\alpha_m > \pi/2$ , it is also necessary to multiply  $V_{CH}$  by minus one (-1) to make  $V_{CH}$  compatible with the definition of  $\alpha'$ .

The artificial  $\partial C_L / \partial \alpha$  is determined using a reference angle of attack  $\alpha_R$ . This  $\alpha_R$  is obtained by subtracting a dynamic stall  $\Delta \alpha$  from  $\alpha'$ . Define:

$$\Delta \alpha_{ds} = 1.076 \ln \left( \frac{0.6}{M_B} \right) \sqrt{b \dot{\alpha} / R V_{CH}} \quad (3.209)$$

where  $b$  is the blade semichord and  $M_B$  is the chordwise Mach number at point  $P_\eta$  modified so that:

$$0.2 \leq M_B \leq 0.6 \quad (3.210)$$

To prevent dynamic stall effects from changing the sign of the lift, we require:

$$\Delta \alpha_{ds} \leq \alpha_m \quad (3.211)$$

Now:

$$\alpha_R = \left| \left[ \alpha' - \Delta \alpha_{os} \left( \frac{\dot{\alpha}}{|\dot{\alpha}|} \right) \right] \right| \quad (2.212)$$

Further, we require that:

$$\frac{\alpha_m}{2} \leq \alpha_R \leq \frac{\pi}{2} \quad (3.213)$$

The static stall angle of attack ( $\alpha_{ss}$ ) and lift coefficient  $C_{L_{ss}}$  are needed. For the typical cambered helicopter airfoil section considered here:

$$\alpha_{ss} = 0.26 - \left[ \frac{0.0065}{0.65 - M_B} \right] \quad (3.214)$$

except that in reverse flow ( $V_{CH} < 0$ ) or for a negative angle of attack ( $\alpha' < 0$ ):

$$\alpha_{ss} = 0.13 \quad (3.215)$$

The static stall  $C_L$  is:

$$C_{L_{ss}} = \alpha_{ss} \left[ \frac{a}{GM(\eta, \psi)} \right] \quad (3.216)$$

where  $GM(\eta, \psi)$  is the compressibility factor, Eq. 3.160).

Now the artificial  $\partial C_L / \partial \alpha$  (labeled  $a_R$ ) can be computed. There are several cases. If  $\alpha_R \leq \alpha_{ss}$ :

$$a_R = a / GM(\eta, \psi) \quad (3.217)$$

If  $\alpha_R > \alpha_{ss}$ :

$$a_R = \text{Max.} \left\{ \begin{array}{l} \left[ a / GM(\eta, \psi) \right] \\ \left| \left( \frac{C_{L_s}}{\alpha_R} \right) \left( \frac{V_R}{V_{CH}} \right) \right| \end{array} \right\} \quad (3.218)$$

where the factor ( $V_R/V_{CH}$ ) accounts for radial flow and  $C_{L_s}$  is:

$$C_{L_s} = \begin{cases} C_{L_{ss}} + \left[ \frac{(1.0 - C_{L_{ss}})(\alpha_R - \alpha_{ss})}{0.28 - \alpha_{ss}} \right] & , (0 < \alpha_R < 0.28) \\ 1.0 & , (0.28 < \alpha_R < \pi/4) \\ \sin \alpha_R & , (\pi/4 < \alpha_R < \pi/2) \end{cases}$$

(3.219)

Finally, the lift coefficient  $C_L$ , including radial flow and dynamic stall effects, is:

$$C_L = a_R \alpha' \quad (3.220)$$

where  $\alpha'$  is defined by Eq. 3.207. To illustrate the results obtained using these procedures, Fig. 23 shows the magnitude of  $C_L$  vs the magnitude of  $\alpha$  (degrees) for the static case ( $\dot{\alpha} = 0$ ) at Mach numbers of 0.2, 0.5, and 0.9.

#### 3.4.3 Airfoil Section Characteristics - Drag

The effect of dynamic stall on drag is represented by using the reference angle of attack  $\alpha_R$ , computed in Subsection 3.4.2 in place of the actual angle of attack. The static stall angle of attack  $\alpha_{ss}$  is used as computed in Subsection 3.4.2 with one exception: for negative angle of attack ( $\alpha' < 0$ ):

$$\alpha_{ss} = 0.07 \quad (3.221)$$

The incompressible drag coefficient  $C_D$  is computed first and a compressibility correction  $C_{D_m}$  is added later.

The computation of the incompressible  $C_D$  involves four formulas: one for the unstalled case plus three stalled cases. Two parameters used in these formulas are:  $C_{D_0}$  ( $C_D$  at zero  $\alpha_R$ ) and  $C_{D_{ss}}$  ( $C_D$  at  $\alpha_R = \alpha_{ss}$ ):

$$C_{D_0} = 0.0087 |V_R / V_{CH}| \quad (3.222)$$

where the factor  $|V_R / V_{CH}|$  corrects  $C_{D_0}$  for radial flow.

$$C_{D_{ss}} = C_{D_0} - .0216 \alpha_{ss} + .40 (\alpha_{ss})^2 \quad (3.223)$$

Now the incompressible  $C_D$  is:

$$C_D = \begin{cases} C_{D_0} - .0216 \alpha_R + .40 (\alpha_R)^2, & (0 < \alpha_R < \alpha_{ss}) \\ C_{D_{ss}} + (.2 - C_{D_{ss}}) \left( \frac{\alpha_R - \alpha_{ss}}{.26 - \alpha_{ss}} \right), & (\alpha_{ss} < \alpha_R < .26) \\ .20 + 1.8 (\alpha_R - .26), & (.26 < \alpha_R < 1.26) \\ 2.0, & (1.26 < \alpha_R) \end{cases} \quad (3.224)$$

The compressibility correction  $C_{D_m}$  is based on the drag divergence Mach number  $M_D$ .

$$M_D = 0.85 - 0.33 |C_L| \quad (3.225)$$

where  $C_L$  is obtained from Eq. 3.220. If the incompressible  $C_D$  is greater than 0.018, then modify  $M_D$ :

$$M_D \rightarrow M_D - \sqrt{C_D - 0.018} \quad (3.226)$$

Also require that:

$$M_o > 0.10 \quad (3.227)$$

Now  $C_{D_m}$  is:

$$C_{D_m} = \begin{cases} 0.0 & , [M < M_o] \\ (M - M_o)^2 & , [0 < (M - M_o) < .15] \\ .0225 + .4(M - M_o - .15) & , [(M - M_o) > .15] \end{cases} \quad (3.228)$$

Finally,  $C_{D_m}$  is added to  $C_D$ :

$$C_D \rightarrow C_D + C_{D_m} \quad (3.229)$$

To illustrate the results obtained using these formulas  $C_D$  vs  $\alpha_R$  (degrees) is shown in Fig. 24 for Mach numbers of: 0.2, 0.5, and 0.9. Note that  $\alpha_R$  is in radians in the formulas quoted here.

#### 3.4.4 Aerodynamic Forces and Performance

The computation of aerodynamic forces, given  $C_L$  and  $C_D$ , is mostly a matter of resolving these forces in various directions. The local aerodynamic forces computed are: airloads (lift) perpendicular to the local relative wind, thrust perpendicular to the tip path plane (TPP), azimuthal force perpendicular to the blade radial axis and parallel to the TPP, the radial force parallel to the blade axis and parallel to the TPP, and the horizontal force in the plane of the direction of flight and parallel to the TPP. The total aerodynamic forces on the rotor computed here are: thrust perpendicular to the TPP, horizontal force in the plane of the direction of flight but parallel to the TPP, and propulsive

force parallel to the direction of flight. The local parasite and induced torque coefficient increments as well as the total rotor torque coefficients are computed. Finally, rotor and total aircraft equivalent lift to drag ratios are computed.

Various angles are needed to resolve these forces. The angle between the local relative wind and the TPP is:

$$\alpha_{TPP} = \alpha(\eta, \psi) - \theta(\eta) - A_1 \cos \psi - B_1 \sin \psi \quad (3.230)$$

where  $A_1$  and  $B_1$  are cyclic pitch components relative to the TPP. Recalling the relationship between cyclic pitch and first harmonic flapping ( $a_1$  and  $b_1$ ) in Gessow-Myers [58]:

$$\alpha_{TPP} = \alpha(\eta, \psi) - \theta(\eta) + b_1 \cos \psi - a_1 \sin \psi \quad (3.231)$$

The angle between the blade element at point  $P_\eta$  and the TPP in the radial direction is assumed to be small. Therefore it is:

$$\frac{\partial z(\bar{\eta}, \psi)}{\partial \bar{\eta}} = q_1 + \left( \frac{\partial \delta_2}{\partial \bar{\eta}} \right) q_2 - q_{1c} \cos \psi - q_{1s} \sin \psi \quad (3.232)$$

where  $q_{1c} = -a_1$  and  $q_{1s} = -b_1$  are the first harmonic sine and cosine components of  $q_1(\psi)$ .

The local airloading (lift) at point  $P_\eta$  is:

$$L(\eta, \psi) = \frac{1}{2} \rho c (\Omega R)^2 (V_{CH})^2 C_L \quad (3.233)$$

which includes dynamic stall effects in the computation of  $C_L$  (Subsection 3.4.2). The program LDS-73 also computes another  $L(\eta, \psi)$  without dynamic stall for comparison with that obtained using Eq. 3.233. This simplified  $L(\eta, \psi)$  is based on  $\alpha(\eta, \psi)$  computed from Eq. 3.154 and a modified version of the  $C_L$  vs  $\alpha$  curve of Fig. 22. The modification to Fig. 22 is to require that  $C_L$  go linearly to zero at  $\alpha = \pm \pi/2$  with the decay starting at  $\alpha \pm (\pi/2 - \alpha_s)$ . Thus the positive- and negative- $\alpha$  portions of the  $C_L$  vs  $\alpha$  curve become symmetrical about  $\alpha = \pm \pi/4$ .

The other aerodynamic forces include components of drag as well as lift. Define the azimuth drag  $D_A$  and the radial drag

$$D_R: \quad D_A = \frac{1}{2} \rho c (\Omega R)^2 (V_{CH})^2 C_D \quad (3.234)$$

$$D_R = \frac{1}{2} \rho c (\Omega R)^2 V_{SP} V_R (.0087) \quad (3.235)$$

where  $V_{SP}$  and  $V_R$  are defined by Eq. 3.205 and Eq. 3.206, respectively. Both the lift  $L(\eta, \psi)$  and the drags  $D_A$  and  $D_R$  will have the dimensions of the factor  $1/2 \rho c (\Omega R)^2$ . Using the normal dimensions for  $\rho$ ,  $c$ ,  $\Omega$ , and  $R$  gives (lb/ft). Since experimental data is normally quoted in (lb/in) the various local forces are output by LDS-73 in (lb/in). Therefore  $L(\eta, \psi)$ ,  $D_A$ , and  $D_R$  will be understood to have dimensions of (lb/in), which involves either measuring the chord ( $c$ ) in inches instead of feet or replacing the  $1/2$  by  $1/24$  in Eq. 3.233 through Eq. 3.235.

The local thrust (lb/in) can now be computed:

$$T_F(\eta, \psi) = L(\eta, \psi) \cos \alpha_{TPP} + D_A \sin \alpha_{TPP} \quad (3.236)$$

The local azimuthal force (lb/in) is:

$$A_F(\eta, \psi) = D_A \cos \alpha_{TPP} - L(\eta, \psi) \sin \alpha_{TPP} \quad (3.237)$$

The local radial force (lb/in) is:

$$R_F(\eta, \psi) = D_R - L(\eta, \psi) \sin \left[ \frac{\partial z(\eta, \psi)}{\partial \eta} \right] \quad (3.238)$$

The local horizontal force (lb/in) is:

$$H_F(\eta, \psi) = R_F(\eta, \psi) \cos \psi + A_F(\eta, \psi) \sin \psi \quad (3.239)$$

The local thrust  $T_F(\eta, \psi)$  and local horizontal force  $H_F(\eta, \psi)$  are integrated over the rotor disk to obtain the total thrust (lb) and the total horizontal force (lb).

$$T = \frac{R'}{2\pi} \int_0^{2\pi} \int_0^1 T_F(\eta, \psi) d\eta d\psi \quad (3.240)$$

$$H = \frac{R'}{2\pi} \int_0^{2\pi} \int_0^1 H_F(\eta, \psi) d\eta d\psi \quad (3.241)$$

where  $R'$  is  $R$  measured in inches to make the units consistent. The total propulsive force  $X(\text{lb})$  is:

$$X = T \sin i - H \cos i \quad (3.242)$$

where  $i$  is the TPP incidence which was originally estimated (Eq. 3.4) by assuming that  $H$  is negligible compared to  $T$ .

The local increments to the total parasite torque, induced torque, and thrust coefficients are computed to show the contribution of each point  $P_\eta$  to the overall rotor performance.

These local increments represent the contribution of a local area, having dimensions  $\Delta\eta$  by  $\Delta\psi$ , around point  $P_\eta$ , to the total coefficients for all  $n_b$  blades. The thrust coefficient increment is:

$$\Delta C_T(\eta, \psi) = \frac{n_b \Delta\eta R'}{\rho \pi R^2 (\Omega R)^2} \frac{\Delta\psi}{2\pi} T_F(\eta, \psi) \quad (3.243)$$

where  $R'$  is  $R$  measured in inches to cancel the inches in  $T_F$  (lb/in). The parasite torque coefficient increment is:

$$\Delta C_{Q_p}(\eta, \psi) = \frac{n_b \eta \Delta\eta R'}{\rho \pi R^2 (\Omega R)^2} \left( \frac{\Delta\psi}{2\pi} \right) D_A \cos \alpha_{TPP} \quad (3.244)$$

The induced torque coefficient increment is:

$$\Delta C_{Q_i}(\eta, \psi) = \frac{n_b \eta \Delta\eta R'}{\rho \pi R^2 (\Omega R)^2} \left( \frac{\Delta\psi}{2\pi} \right) \left[ -L(\eta, \psi) \sin \alpha_{TPP} \right] \quad (3.245)$$

The total  $C_T$ ,  $C_{Q_p}$ , and  $C_{Q_i}$  are obtained by summing these increments over the rotor disc. The total torque coefficient is the sum of the

parasite and induced contributions.

$$C_Q = C_{Q_p} + C_{Q_i} \quad (3.246)$$

The overall aircraft lift to equivalent drag ratio is a useful measure of aerodynamic efficiency.

$$L/D_E = \mu C_T / C_Q \quad (3.247)$$

The rotor lift to equivalent drag ratio removes the fuselage and hub drag giving a measure of the aerodynamic efficiency of the rotor in isolation.

$$(L/D_E)_R = \mu C_T / (C_Q - \mu C_x) \quad (3.248)$$

where  $C_x$  is the propulsive force coefficient:

$$C_x = \frac{X}{\rho \pi R^2 (\Omega R)^2} \quad (3.249)$$

Finally, an angle of attack distribution  $\alpha(\eta, \psi)$  is required for use in the computation of the bound circulation distribution, either for another iteration of LDS-73 or as input to a tip vortex geometry computation by WG-71. Since all circulation computations use the input, constant lift curve slope  $a$  the  $\alpha(\eta, \psi)$  is adjusted to give the correct lift when  $\partial C_L / \partial \alpha = a$ .

$$\alpha(\eta, \psi) = C_L / a \quad (3.250)$$

where  $C_L$  is obtained from Eq. 3.220.

This completes the computation of airloads.

## SECTION 4

### ROTOR TIP VORTEX GEOMETRY COMPUTATION

The concentrated tip vortex line is the dominant part of the rotor wake (see Subsection 1.1). It is, therefore, worth expending extra effort to obtain a more accurate estimate for the tip vortex-line geometry than the basic rigid-wake assumption (Subsection 1.5.1). The more accurate tip-vortex geometry is called the distorted tip-vortex geometry, compared to the normal rigid-wake-geometry assumption. The computation of this distorted geometry consists of the computation of the tip-vortex distortion  $\vec{D}(\psi, \delta)$ . This  $\vec{D}(\psi, \delta)$  is the displacement of point  $P_\eta$  on the tip vortex due to the induced velocity (see Subsection 1.5).

A computer program (WG-71) has been developed to compute the tip-vortex distortion  $\vec{D}(\psi, \delta)$ . This program is designed to be used together with the airloads program LDS-73. The wake geometry program WG-71 uses a circulation distribution which is computed by LDS-73 and which remains constant throughout the computation of  $\vec{D}(\psi, \delta)$ . The relationship between the airloads computation (LDS-73) and the tip-vortex-geometry computation (WG-71) is shown in Fig. 3.

The computation of the tip-vortex distortion  $\vec{D}(\psi, \delta)$  is conceptually very simple. The induced velocity at various points  $P_\eta$  on the tip vortex is computed as a function of age (time)  $\delta$ . This induced velocity is integrated over time to obtain  $\vec{D}(\psi, \delta)$ . The problem is that the induced velocity is a function of the tip vortex geometry which is, in turn, a function of  $\vec{D}(\psi, \delta)$ . Thus, as the computation proceeds and the current estimate of  $\vec{D}(\psi, \delta)$  changes, it is necessary to recompute, or update, the induced velocity. This repeated updating of the induced velocity is very expensive, which means that a simple, brute-force tip-vortex-geometry computation is very expensive. It is, therefore, important to develop various refinements to the tip-vortex-geometry computation which reduce the expense of updating. These refinements greatly reduce

the expense of the computation by reducing the amount of repetition required. They also greatly complicate what is basically a simple problem.

The distortion computation will be described in two stages. First, the fundamental computation is described to give a clear understanding of the basic approach used. Then the various refinements are described. These refinements complicate the computation, but they reduce the expense of the computation by reducing the amount of updating required.

#### 4.1 Fundamental Distortion Computation

This subsection describes the fundamental distortion computation without the complication of the various refinements designed to reduce the amount of updating required. When the fundamental distortion computation is understood, the various refinements will be considered in Subsection 4.2. Since it is very important to save computational expense by the use of the simplest wake model which can give adequate accuracy, the choice of wake models will also be reviewed.

##### 4.1.1 Basic Notation

A review of Subsection 1.5 will clarify the nomenclature and notation used. It is important to understand the differences between the notation used for airloads computations and that used for tip vortex distortion computations. The general point  $P_\eta$ , at which the induced velocity is computed, is located on the  $\eta$  blade for airloads computations, but it is located on the tip vortex for distortion computations. For airloads computations, the age of point  $P_\eta$  is always zero while the age of point  $P_\ell$  is labeled  $\delta$ . For distortion computations, the age of point  $P_\eta$  can be nonzero and is labeled  $\delta$  while the age of point  $P_\ell$  becomes  $\delta_\ell$ . This change in the definition of  $\delta$  must be remembered.

The points  $P_\eta$  and  $P_\ell$  are identified by the parameters  $(\eta, \psi, \delta)$  and  $(\ell, \phi, \delta_\ell)$ , respectively. These parameters are measured

with respect to the fundamental skewed helix not the actual distorted tip vortex. Thus, these parameters remain independent of changes in the distortion. For example:  $\eta$  and  $l$  are always equal to unity for the tip vortex. To obtain the location of point  $P_\eta$  or point  $P_l$ , the corresponding point on the fundamental skewed helix ( $P_\eta^F$  or  $P_l^F$ ) is found using these parameters. Then the appropriate distortion,  $\vec{D}(\psi, \delta)$  or  $\vec{D}(\phi, \delta_l)$ , provides a vector linking point  $P_\eta^F$  or point  $P_l^F$  with the actual point  $P_\eta$  or point  $P_l$  on the distorted tip vortex.

The function  $\vec{D}(\psi, \delta)$  is only evaluated for a discrete set of  $\psi$  and  $\delta$ .

$$\psi = 0, \Delta\psi, 2\Delta\psi, \dots, 2\pi \quad (4.1)$$

$$\delta = 0, \Delta\psi, 2\Delta\psi, \dots, 2\pi m \quad (4.2)$$

The  $\Delta\psi$  used for a distortion computation is chosen to be the same as the  $\Delta\phi$  used for the corresponding airloads computation. This is done to ensure that the distortion is computed at the end points of the tip-vortex line segments used in the airloads computation (i.e., at points  $P_l$  for the airloads computation). The azimuth angle  $\psi$  only varies over the range 0 to  $2\pi$  because the wake geometry is assumed to be cyclic for the steady-state-flight cases considered here. In other words if photographs of the rotor and its wake are taken at two different times, chosen such that the azimuth angles of the rotor blades are identical in both photographs, then the wake geometry will also be identical.

The azimuth angle  $\psi$  can be thought of as identifying the general location of point  $P_\eta$  in the wake. The age  $\delta$  locates point  $P_\eta$  relative to the current position of the rotor. Since only the wake near the rotor is of interest for airloads computations, the tip-vortex distortion is only computed for  $\delta$  ranging from 0 to  $2\pi m$ . A typical value of  $m$  is two.

The distortion  $\vec{D}(\phi, \delta_l)$  is the same function as  $\vec{D}(\psi, \delta)$ , but

is evaluated at point  $P_\ell$  instead of at point  $P_\eta$ . Therefore,  $\phi$  and  $\delta_\ell$  must also come in increments of  $\Delta\psi$  to be compatible with  $\psi$  and  $\delta$ . The range of  $\delta_\ell$  will be discussed in Subsection 4.1.3. The desired range of  $\phi$  is 0 to  $2\pi$ . However, solving Eq. 1.2 for  $\phi$  yields:

$$\phi = \psi + \zeta + \delta - \delta_\ell \quad (4.3)$$

Examination of this equation for  $\psi$  and  $\zeta$  between 0 and  $2\pi$  and for  $\delta$  and  $\delta_\ell$  between 0 and  $2\pi$  shows that  $\phi$  is not restricted to the range 0 to  $2\pi$ . Thus, it must be understood that when evaluating functions which are cyclic in azimuth angle, such as  $\vec{D}(\phi, \delta_\ell)$  and  $\gamma_{bv}(\phi)$ , at azimuth angle  $\phi$ , the principle value of  $\phi$  is used (i.e., the appropriate integer multiple of  $2\pi$  is added or subtracted so that:  $0 \leq \phi \leq 2\pi$ ).

The same  $x, y, z$  coordinate system with origin at point  $P_\eta$  is used for distortion computations as was used for airloads computations (Subsection 3.2.3). The definitions of  $\vec{a}$  and  $\vec{b}$  (Eqs. 3.9 and 3.10) remain the same as well. The components of  $\vec{a}$  and  $\vec{b}$  are different, however, because point  $P_\eta$  is now in the wake instead of on the  $\eta$  blade.

#### 4.1.2 Wake Models and Circulation

The wake models used are generally described in Section 2. There are some differences between the wake models used by WG-71 and those used by LDS-73. These differences are primarily because the airloads program LDS-73 was rewritten more recently than the wake geometry program WG-71. Thus, WG-71 does not have provision for the tip vortex sheet plus vortex line (VSVL) model described in Subsection 2.5.3 or for vortex sheets having a vortex core. However, WG-71 retains provisions for an  $n$  trailing vortex line model (Subsection 2.2), which was discarded by LDS-73 to reduce the size of the QMAT matrix. Finally, the trailing and shed vortex sheet models used by WG-71 are somewhat more complicated than those used by LDS-73.

The fundamental difference between the WG-71 and LDS-73 inboard trailing vortex sheet models is in the determination of  $\ell_i(\phi)$ , the outboard edge of the vortex sheet. For LDS-73,  $\ell_i(\phi)$  is computed by requiring that the area under the curve  $\gamma(\eta, \phi)$  vs.  $\eta$  be the same for the model bound circulation distribution as for the actual bound circulation distribution.

$$\gamma_{bv}(\phi) [1.0 - 0.5 \ell_i(\phi) - 0.5 \ell_1] = \int_{\ell_1}^{\ell_2} \gamma(\eta, \phi) d\eta \quad (4.4)$$

where  $\gamma_{bv}(\phi)$  is defined in Subsection 2.8.1. The  $\ell_i(\phi)$  obtained from Eq. 4.6 is then averaged over  $\phi$  to obtain  $\ell_2$ . If this  $\ell_2$  is greater than an input  $\ell_2$ , the input value is used. This technique was at one time used for airloads computations and the actual  $\ell_i(\phi)$  was used instead of the average value  $\ell_2$ . This led to difficulties with circulation iteration convergence and was abandoned in favor of the average  $\ell_2$ . This, in turn, was replaced by an input  $\ell_i(\phi)$  in LDS-73; however, WG-71 has not been updated to include this option.

WG-71 has provision for either a one segment or two segment shed vortex-sheet model, see Subsection 2.8.2. The two-segment model is used with the inboard trailing vortex-sheet model. When a shed vortex-sheet model is used, the trailing vortex sheet or line segments have a linear circulation variation to conserve circulation.

Since point  $P_\eta$  is not on a rotor blade in distortion computations, the near wake effects associated with the rotor blade do not apply. However, the computation of the induced velocity contributions of the tip-vortex-line and shed-vortex-sheet segments adjacent to point  $P_\eta$  must be done with special care. The use of the normal straight tip vortex-line segments for this case gives zero contribution which is unrealistic. The solution is to replace these two straight tip vortex-line segments with a circular arc segment passing through the three different end points of these segments. This circular arc segment has the same vortex core radius

as the rest of the tip vortex. The geometry and the contribution to the induced velocity at point  $P_\eta$  of this circular arc segment are derived in Appendix C. The problem with the adjacent shed vortex sheet segments is the edge singularity associated with any vortex sheet. This is avoided by replacing these two adjacent vortex sheet segments with one big vortex sheet segment which has point  $P_\eta$  in the middle.

The information actually input to WG-71 from LDS-73 is the angle-of-attack distribution  $\alpha(\eta, \psi)$  in degrees. The bound circulation distribution is obtained from:

$$\gamma(\eta, \psi) = \frac{a}{360} (\eta + \mu \sin \psi) \alpha(\eta, \psi) \quad (4.5)$$

which is analogous to Eq. 3.1. This bound circulation distribution is used directly for the  $n$  trailing vortex-line case, where  $n$  is the number of  $\eta$  stations plus one. Otherwise, the circulation models of Subsection 2.8 are used as necessary.

The vortex core radii used by WG-71 are normally the same as those used by LDS-73. A table of ages for tip-vortex core bursting is also obtained from LDS-73. There is no provision for vortex sheet vortex cores in WG-71, again because this is a recent addition to LDS-73 which did not make much difference in the final answers.

#### 4.1.3 Wake-Geometry Extrapolation

The tip vortex distortion is only computed for the wake which is within  $2\pi m$  of the rotor (i.e., for  $0 \leq \delta \leq 2\pi m$ ). When computing the distortion  $\hat{D}(\psi, \delta)$  at point  $P_\eta$  it is clearly necessary to consider the induced velocity contributions of all of the wake within  $2\pi M$  of point  $P_\eta$ , where  $M$  is normally at least as large as  $m$ . Thus,  $\delta_\ell$  will range from 0 to  $\delta + 2\pi M$  for any given  $\delta$  and will have a maximum range of 0 to  $2\pi(m + M)$ . This implies a need to know the geometry of the tip vortex for angles  $\delta_\ell$  greater than  $2\pi m$ .

One solution to this problem is to simply neglect all wake for ages greater than  $2\pi m$ . This means that the  $\vec{D}(\psi, \delta)$  calculated for  $\delta$  near  $2\pi m$  will be very inaccurate. This is due to the neglect of some nearby wake which can be expected to make a large contribution to the induced velocity at point  $P_\eta$  and hence to  $\vec{D}(\psi, \delta)$ . Thus,  $m$  must be approximately doubled so that the inaccurate  $\vec{D}(\psi, \delta)$  computed for  $\delta$  between  $2\pi(m - M)$  and  $2\pi m$  can be discarded and still leave an adequate amount of accurate  $\vec{D}(\psi, \delta)$  near the rotor.

A much more economical and more accurate solution is to use extrapolation of the tip-vortex geometry for  $\delta_\ell$  greater than  $2\pi m$ . This allows all of the wake within  $2\pi M$  in age of any point  $P_\eta$  to be included in a distortion computation, just as all of the wake within  $2\pi m$  of any point  $P_\eta$  on the rotor is included in an airloads computation. This is the solution used by WG-71. The extrapolation scheme chosen assumes that the distortion parallel to the TPP remains constant for  $\delta_\ell > 2\pi m$ , while the distortion perpendicular to the TPP is computed, using a mean induced velocity for  $\delta_\ell > 2\pi m$ . This implies the following relations for  $\delta_\ell > 2\pi m$ :

$$D_1(\phi, \delta_\ell) = D_1(\phi, 2\pi m) \quad (4.6)$$

$$D_2(\phi, \delta_\ell) = D_2(\phi, 2\pi m) \quad (4.7)$$

$$D_3(\phi, \delta_\ell) = D_3(\phi, 2\pi m) + (\lambda - \mu \tan i)(\delta_\ell - 2\pi m) \quad (4.8)$$

where the components of  $\vec{D}(\phi, \delta_\ell)$  are defined by Eq. 3.17 and  $\lambda$  is an input mean inflow, normally the same as for a rigid wake model.

#### 4.1.4 Iteration Scheme

As discussed at the beginning of this section, it is necessary to know the distortion in order to be able to compute the distortion. This means that an iteration scheme is required. Any iteration scheme must also include provisions for starting the iteration. Various possible iteration and starting schemes are

described in this subsection and the reasons for choosing the particular schemes used by WG-71 are indicated.

The basic requirement for starting the  $\vec{D}$  iteration is an initial assumption for the wake geometry. One possibility is to assume that the rotor is instantaneously started from rest, which implies that there is initially no wake. As the rotor rotates new wake is generated and the tip-vortex distortion is computed for this new wake as it is generated. This scheme is analogous to the neglect of all wake for  $\delta_l > 2\pi m$ , as discussed in Subsection 4.1.3. The problem with this starting scheme is similar to the problem with the neglect of wake for  $\delta_l > 2\pi m$ . The  $\vec{D}$  computed for the first  $2\pi m$  or so in age is very inaccurate and extra computation is required to achieve a converged result.

The scheme used by WG-71 is to start with  $2\pi m$  of assumed wake geometry. Normally, the rigid-wake assumption is used for this purpose. As the computation proceeds, the rotor rotates generating new wake. The tip-vortex distortion is computed for this new calculated wake, but not for the old assumed wake, which retains its original, assumed geometry. As new calculated wake is generated, the rotor moves away from the assumed wake. Eventually enough calculated wake ( $2\pi m$  in age) is generated to provide either a calculated  $\vec{D}$  or an extrapolation of the calculated  $\vec{D}$  for all purposes and the assumed wake is no longer needed. This starting scheme gives rapid convergence and is recommended.

After the tip-vortex distortion computation is started by generating the first  $2\pi m$  of new wake, a scheme for the rest of the computation is required. Two possibilities will be considered: continuous computation and iteration. For the continuous computation scheme, the rotor continues to advance generating new wake. However, only the distortion of the tip vortex within  $2\pi m$  of the rotor is being computed. Therefore, every time the rotor generates  $\Delta\psi$  of new calculated tip vortex ( $\delta = 0$  to  $\Delta\psi$ ), the oldest remaining

$\Delta\psi$  of calculated tip vortex is dropped ( $\delta = 2\pi m$  to  $2\pi m + \Delta\psi$ ) from the computation. Thus, the calculated table of  $\hat{D}(\psi, \delta)$  is limited to  $0 < \delta < 2\pi m$ . As discussed in Subsection 4.1.3, an extrapolated  $\hat{D}(\phi, \delta_\ell)$  is available for  $\delta_\ell > 2\pi m$ . This continuous computation continues until the calculated  $\hat{D}(\psi, \delta)$  converges.

For the iterative scheme, no more new calculated wake is generated beyond the starting  $2\pi m$ . Instead a new iteration is begun. This new iteration starts with an assumed wake consisting of  $2\pi m$  of distorted wake from the previous iteration plus  $2\pi(M - m)$  of extrapolated distortion. The computation then proceeds as in the starting scheme, but with this revised initial wake-geometry assumption. The iteration is repeated until distortion convergence is achieved. Normally, two or three iterations are required. This iteration scheme is used by WG-71 because it is slightly more convenient for use with some of the refinements described in Subsection 4.2. Basically, either continuous computation or iteration can be used satisfactorily.

#### 4.1.5 Basic Distortion Iteration

A simplified flow chart for the basic distortion iteration is given in Fig. 25. This flow chart represents one iteration of the fundamental distortion computation, the brute-force approach to tip vortex-geometry computation. The more complicated development of this technique used by WG-71 will be described in Subsection 4.2.

The first step is to initialize  $\vec{D}_N(\psi)$  and  $\delta_D$  which will be defined later. Now consider the outer loops on  $\delta_M$  and  $\delta$ . Advancing  $\delta_M$  by  $\Delta\psi$  causes the boundary between assumed and calculated wake to move forward by  $\Delta\psi$  and it causes a segment ( $\Delta\psi$ ) of new calculated wake to be generated. Thus,  $\delta_M$  starts at  $\Delta\psi$ , representing the first increment of new calculated wake. When  $\delta_M = 2\pi m$ , the  $D(\psi, \delta)$  for  $2\pi m$  of tip vortex has been calculated and the iteration is over. The  $\delta$  loop is updating, except for the last step when  $\delta = \delta_M$ . For this brute force approach, complete updating is done at every step in  $\delta_M$ . If no updating were done, the  $\delta$  loop would be eliminated and  $\delta$  would always be equal to  $\delta_M$ .

The next loop is on  $\psi$ . Since both  $\delta$  and  $\psi$  are now determined, it is possible to locate point  $P_\eta$  using the current best estimate of  $\vec{D}(\psi, \delta)$  (see Subsection 4.1.6). The induced velocity totals  $\Sigma \vec{q}$ ,  $\vec{q}_{BV}$ , and  $\Delta \vec{q}$  are all set equal to zero here. These totals are accumulated for each point  $P_\eta$  and will be needed later. The total induced velocity at point  $P_\eta$  at age  $\delta$  is  $(\Sigma \vec{q} + \vec{q}_{BV})$ , where  $\vec{q}_{BV}$  is the contribution of the bound vorticity. The contribution of all the new wake generated by the last  $\Delta\psi$  increment to  $\delta_\ell$  (i.e., the wake between  $\delta_\ell = 0$  and  $\delta_\ell = \Delta\psi$ ) to the induced velocity at point  $P_\eta$  is called  $\Delta \vec{q}$ .

The next loop is on  $\zeta$ . This is done to include the contributions to the induced velocity at point  $P_\eta$  of the wake and the bound vorticity of each blade.

The next loop is on  $\delta_\ell$ . This represents integration up the wake from  $\delta_\ell = \delta + 2\pi M$  to  $\delta_\ell = 0$ . Given  $\psi$ ,  $\zeta$ ,  $\delta$ , and  $\delta_\ell$ , the value of  $\phi$  is determined by Eq. 4.3. Thus, the  $\delta_\ell$  loop can be thought of as a  $\phi$  loop. When WG-71 was written this loop was considered a  $\phi$  loop and the variable names in WG-71 reflect this. The loop will be explained here as a  $\delta_\ell$  loop, however, because this approach is much easier to understand.

Before the  $\ell$  loop starts, another induced velocity total  $\vec{q}_s$  is set equal to zero. This  $\vec{q}_s$  is the contribution to the induced velocity at point  $P_\eta$  of all of the wake of one blade between the ages  $\delta_\ell$  and  $\delta_\ell - \Delta\psi$ . The last value of  $\vec{q}_s$  (for  $\delta_\ell = 0$ ) is the only one actually used by the basic distortion iteration. In fact, if the  $\zeta$  loop were placed inside the  $\delta_\ell$  loop,  $\Delta\vec{q}$  could be defined directly and  $\vec{q}_s$  would not be needed here. However, all values of  $\vec{q}_s$  will be needed by the near/far wake scheme (Subsection 4.2.1), so they are defined here to minimize the changes required.

The  $\ell$  loop provides for the contributions to the induced velocity of the wake and bound vorticity associated with the various radial stations  $\ell$ . Since  $\ell$ ,  $\phi$ , and  $\delta_\ell$  are now all known, the location of point  $P_\ell$  can be determined using the current best estimate of  $\vec{D}(\phi, \delta_\ell)$  (see Subsection 4.1.6). The vectors  $\vec{a}$  and  $\vec{b}$  connecting point  $P_\eta$  with the various points  $P_\ell$  can now be determined. This data can then be used to compute the actual contributions to the induced velocity at point  $P_\eta$  from the various wake elements ( $\vec{q}$ ) and, when  $\delta_\ell = 0$ , from the bound vorticity ( $\Delta\vec{q}_{BV}$ ). The details of computing  $\vec{a}$ ,  $\vec{b}$ ,  $\vec{q}$ , and  $\vec{q}_{BV}$  will be covered in Subsections 4.1.7 and 4.1.8. The computed  $\vec{q}$  is added to the totals  $\Sigma\vec{q}$  and  $\vec{q}_s$ . If  $\delta_\ell = 0$ , then  $\Delta\vec{q}_{BV}$  is added to  $\vec{q}_{BV}$ . This ends the  $\ell$  loop.

Working outward through the nest of loops,  $\delta_\ell$  and  $\phi$  are changed by  $\Delta\psi$  and a test is made for the end of the  $\delta_\ell$  loop. At the end of the  $\delta_\ell$  loop,  $\delta_\ell = 0$ , which implies that the current value of  $\vec{q}_s$  can be added to  $\Delta\vec{q}$ . Because this is inside the  $\zeta$  loop, there will be a contribution to  $\Delta\vec{q}$  from each blade as  $\zeta$  changes.

When the  $\zeta$  loop is finished, the induced velocity at point  $P_\eta$  has been computed. This has involved summing contributions from various radial stations ( $\ell$ ) and various blades ( $\zeta$ ) as well as an integration over the azimuthal extent of the wake ( $\delta_\ell$ ). Now the average induced velocity at point  $P_\eta$  between ages  $\delta - \Delta\psi$  and  $\delta$  is:

$$\vec{q}_0(\psi) = \sum \vec{q} + \vec{q}_{bv} - 0.5 \Delta \vec{q} \quad (4.9)$$

where  $\vec{q}_{bv}$  has already been averaged (see Subsection 4.1.7).

At this point the main  $\psi$  loop ends and the computation of  $\vec{D}(\psi, \delta)$  occurs inside a separate  $\psi$  loop. This is done to avoid the problem of trying to use a table of distortion where the boundary between computed  $\vec{D}$  and assumed  $\vec{D}$  is  $\delta$  for azimuth angles less than  $\psi$ , and  $\delta - \Delta\psi$  for azimuth angles greater than or equal to  $\psi$ . Before a new  $\vec{D}(\psi, \delta)$  is computed, the old value is stored as  $\vec{D}_0(\psi)$  and the current value of  $\delta$  is stored as  $\delta_D$ . Now, the incremental distortion is computed as the averaged induced velocity times the time increment ( $\Delta\psi$ ):

$$\vec{D}(\psi, \delta) = \vec{D}(\psi, \delta - \Delta\psi) + \Delta\psi \vec{q}_0(\psi) \quad (4.10)$$

To start this incremental computation of  $\vec{D}(\psi, \delta)$ , a value for  $\vec{D}(\psi, 0)$  is required. At age  $\delta = 0$ , there has been zero time for the wake to accumulate distortion since leaving the rotor blade; therefore:

$$\vec{D}(\psi, 0) = 0.0 \quad (4.11)$$

The  $\delta$  loop ends when  $\delta = \delta_M$ .

After the boundary age,  $\delta_M$ , is incremented, the assumed value of  $\vec{D}(\psi, \delta_M - \Delta\psi)$  is moved from  $\vec{D}_N(\psi)$  to  $\vec{D}_S(\psi)$  and the assumed value of  $\vec{D}(\psi, \delta_M)$  is stored in  $\vec{D}_N(\psi)$ . The only function of  $\vec{D}_N(\psi)$  is as an intermediary between  $\vec{D}$  and  $\vec{D}_S$ . For the basic distortion iteration  $\vec{D}_0$  could be used instead of  $\vec{D}_N$ , but this is not true for WG-71. The function of  $\vec{D}_0(\psi)$  and  $\vec{D}_S(\psi)$  is to aid in the location

of point  $P_\eta$  (see Subsection 4.1.6).

The  $\delta_M$  loop ends when  $\delta_M = 2\pi m$ . At this point the distortion of the  $2\pi m$  of wake nearest the rotor has been computed and an iteration has been completed. There is no test for convergence of the distortion computation in WG-71. Instead, the number of iterations is an input (normally two is sufficient). Distortion convergence is determined by examination of tip vortex geometry plots for successive iterations.

The computation is arranged such that only one complete  $\vec{D}$  table is required. At the start of an iteration, this table contains the assumed  $\vec{D}$ . As the computation proceeds, the computed  $\vec{D}$  steadily replaces the assumed  $\vec{D}$  in the table. The boundary between the computed  $\vec{D}$  and the assumed  $\vec{D}$  is age  $\delta_M$ . At the end of an iteration, the table contains only computed  $\vec{D}$ . Recall that at the start of a new iteration, the computed  $\vec{D}$  from the previous iteration becomes the assumed  $\vec{D}$  for the new iteration. Thus the  $\vec{D}$  table does not need to be changed to start a new iteration.

#### 4.1.6 Location of Points $P_\ell$ and $P_\eta$

The location of points  $P_\ell$  and  $P_\eta$  requires careful consideration because it is important to use all of the available information to achieve the best possible estimate. The basic problem is that the best estimate of the distortion  $\vec{D}$  changes as a distortion iteration proceeds. Furthermore, in the middle of a distortion iteration, the  $\vec{D}$  for the computed wake is more accurate than the  $\vec{D}$  for the assumed wake, since it has been computed more recently. The estimation of the distortion at points  $P_\ell$  and  $P_\eta$  is therefore more complicated than simply using  $\vec{D}(\phi, \delta_\ell)$  and  $\vec{D}(\psi, \delta)$ .

Consider the state of the  $\vec{D}$  table at a point in the middle of an iteration. The table will have three distinct areas containing different types of  $\vec{D}$ . For ages greater than or equal to  $\delta_M$ , the table will contain assumed  $\vec{D}$ . This is the least accurate

type of  $\vec{D}$  since it is the oldest. For ages less than or equal to  $\delta_D$ , the table will contain computed values of  $\vec{D}$  which have just been updated. This is the most accurate type of  $\vec{D}$  since it is the most recently computed. For ages greater than  $\delta_D$ , but less than  $\delta_M$ , the table will contain computed  $\vec{D}$  values which have not been updated as recently as the  $\vec{D}$  of the preceding section, if it has been updated at all. This intermediate section of the  $\vec{D}$  table will not exist if  $\delta_D$  happens to be equal to  $\delta_M$ .

While  $\vec{D}(\psi, \delta)$  describes the distortion at point  $P_\eta$ , it is not always the most accurate available description. Define  $\vec{D}_\eta(\psi, \delta)$  as the best possible estimate for the distortion at point  $P_\eta$ . Then for  $\delta \leq \delta_D$ :

$$\vec{D}_\eta(\psi, \delta) = \vec{D}(\psi, \delta) \quad (4.12)$$

For  $\delta_D < \delta < \delta_M$ :

$$\vec{D}_\eta(\psi, \delta) = \vec{D}(\psi, \delta_D) + \vec{D}(\psi, \delta) - \vec{D}_0(\psi) \quad (4.13)$$

and for  $\delta \geq \delta_M$ :

$$\vec{D}_\eta(\psi, \delta) = \vec{D}(\psi, \delta_D) + \vec{D}(\psi, \delta_M) - \vec{D}_0(\psi) + \vec{D}(\psi, \delta) - \vec{D}_s(\psi) \quad (4.14)$$

Consider the case  $\delta \geq \delta_M$  (Eq. 4.14). For this case, the distortion accumulated up to age  $\delta_D$  is estimated by  $\vec{D}(\psi, \delta_D)$ , which has just been updated. The distortion accumulated between age  $(\delta_D + \Delta\psi)$  and age  $(\delta_M - \Delta\psi)$  is estimated by  $\vec{D}(\psi, \delta_M) - \vec{D}_0(\psi)$ , which is calculated distortion not updated as recently as  $\vec{D}(\psi, \delta_D)$ . Finally, the distortion accumulated between age  $\delta_M$  and  $\delta$  is estimated by  $\vec{D}(\psi, \delta) - \vec{D}_s(\psi)$ , which is assumed distortion.

For point  $P_\ell$  the same technique is used. Define  $\vec{D}_\ell(\phi, \delta_\ell)$  as the best available estimate of the distortion at point  $P_\ell$ . Then for  $\delta_\ell \leq \delta_D$ :

$$\vec{D}_l(\phi, \delta_l) = \vec{D}(\phi, \delta_l) \quad (4.15)$$

for  $\delta_D < \delta_l < \delta_M$ :

$$\vec{D}_l(\phi, \delta_l) = \vec{D}(\phi, \delta_D) + \vec{D}(\phi, \delta_l) - \vec{D}_D(\phi) \quad (4.16)$$

and for  $\delta_l \geq \delta_M$ :

$$\vec{D}_l(\phi, \delta_l) = \vec{D}(\phi, \delta_D) + \vec{D}(\phi, \delta_M) - \vec{D}_D(\phi) + \vec{D}(\phi, \delta_l) - \vec{D}_M(\phi) \quad (4.17)$$

Extrapolation is never necessary to find  $\vec{D}_\eta(\psi, \delta)$  since  $\delta \leq 2\pi m$ . However,  $\delta_l$  can exceed  $2\pi m$  and in this case, extrapolation becomes necessary for  $\vec{D}_l(\phi, \delta_l)$ , (see Subsection 4.1.3). The extrapolation technique includes computing  $\vec{D}_l(\phi, \delta_l)$  for  $\delta = 2\pi m$  and then adding  $(\lambda - \mu \tan i)(\delta_l - 2\pi m)$  to the  $\vec{k}$  component of  $\vec{D}_l(\phi, 2\pi m)$ , (see Eqs. 4.6, 4.7, and 4.8).

Once the distortions  $\vec{D}_\eta(\psi, \delta)$  and  $\vec{D}_l(\phi, \delta_l)$  have been evaluated, the locations of points  $P_\eta$  and  $P_l$  are easily found. For distortion computations, the absolute locations of points  $P_l$  and  $P_\eta$  are not needed. What is needed is the vector ( $\vec{a}$  or  $\vec{b}$ ) connecting point  $P_\eta$  with point  $P_l$ . The formulas for the vector components of  $\vec{a}$  and  $\vec{b}$  will be developed when the computation of the various contributions to the induced velocity is described (Subsections 4.1.7 and 4.1.8).

#### 4.1.7 Wake Contribution to Induced Velocity

The computation of the induced velocity contribution of the wake in WG-71 is very similar to the induced velocity computation in LDS-73 (Subsections 3.2.3, 3.2.5, and 3.2.6). The differences between these computations are due to slightly different wake models (Subsection 4.1.2) and due to differences in the locations of points  $P_l$  and  $P_\eta$ . Point  $P_\eta$  is located on a rotor blade for airloads computations and has no distortion. For distortion computations, point  $P_\eta$  is located on the tip vortex. Thus,  $\vec{D}_\eta(\psi, \delta)$

must be included in distortion computations. At point  $P_\ell$  the distortion  $\vec{D}(\phi, \delta)$  is simply looked up in the table of  $\vec{D}$  for airloads computations. For distortion computations  $\vec{D}_\ell(\phi, \delta_\ell)$  must be used (Subsection 4.1.6). It is also important to recall that the notation  $\delta$  has different meanings in WG-71 and LDS-73 (Subsection 4.1.1).

The vectors  $\vec{a}$  and  $\vec{b}$  are vectors beginning at point  $P_\eta$  and ending at various points  $P_\ell$  (which are labeled points  $P_a$  and  $P_b$ , as necessary).

Recall the components of  $\vec{a}$  and  $\vec{b}$ :

$$\vec{a} = x_a \vec{i} + y_a \vec{j} + z_a \vec{k} \quad (3.9)$$

$$\vec{b} = x_b \vec{i} + y_b \vec{j} + z_b \vec{k} \quad (3.10)$$

where  $\vec{i}$ ,  $\vec{j}$ , and  $\vec{k}$  are defined in Subsection 3.2.3. Define the components of  $\vec{D}_\eta(\psi, \delta)$  and  $\vec{D}_\ell(\phi, \delta_\ell)$  as:

$$\vec{D}_\eta(\psi, \delta) = D_{\eta x}(\psi, \delta) \vec{i} + D_{\eta y}(\psi, \delta) \vec{j} + D_{\eta z}(\psi, \delta) \vec{k} \quad (4.18)$$

$$\vec{D}_\ell(\phi, \delta_\ell) = D_{\ell x}(\phi, \delta_\ell) \vec{i} + D_{\ell y}(\phi, \delta_\ell) \vec{j} + D_{\ell z}(\phi, \delta_\ell) \vec{k} \quad (4.19)$$

Now consider the trailing wake. Point  $P_a$  is at the end of the vortex line (or vortex sheet) segment having the smallest age. Thus, point  $P_a$  is identified by  $(\ell, \phi, \delta_\ell)$  while point  $P_b$  is identified by  $(\ell, \phi - \Delta\psi, \delta_\ell + \Delta\psi)$ . The equations for the components of  $\vec{a}$  and  $\vec{b}$  are analogous to Eqs. 3.18 through 3.23. and are derived the same way:

$$x_a = \ell \sin \phi - \eta \sin \psi + D_{\ell x}(\phi, \delta_\ell) - D_{\eta x}(\psi, \delta) \quad (4.20)$$

$$x_b = l \sin(\phi - \Delta\psi) - \eta \sin\psi + D_{lx}(\phi - \Delta\psi, \delta_l + \Delta\psi) - D_{\eta x}(\psi, \delta) \quad (4.21)$$

$$y_a = l \cos\phi - \eta \cos\psi + \mu(\delta_l - \delta) + D_{ly}(\phi, \delta_l) - D_{\eta y}(\psi, \delta) \quad (4.22)$$

$$y_b = l \cos(\phi - \Delta\psi) - \eta \cos\psi + \mu(\delta_l + \Delta\psi - \delta) + D_{ly}(\phi - \Delta\psi, \delta_l + \Delta\psi) - D_{\eta y}(\psi, \delta) \quad (4.23)$$

$$z_a = (\delta_l - \delta) \mu \tan i - a_o(l - \eta) + D_{lz}(\phi, \delta_l) - D_{\eta z}(\psi, \delta) \quad (4.24)$$

$$z_b = (\delta_l + \Delta\psi - \delta) \mu \tan i - a_o(l - \eta) + D_{lz}(\phi - \Delta\psi, \delta_l + \Delta\psi) - D_{\eta z}(\psi, \delta) \quad (4.25)$$

For the tip vortex,  $\eta$  is unity. The factor  $(\delta_l - \delta)$  is written as  $(\psi + \zeta - \phi)$  in WG-71, which is equivalent (see Eq. 4.3).

For the tip vortex line, case  $\gamma_a$  is computed using Subsection 2.8.1. The induced velocity contribution is:

$$\vec{q} = \gamma_c(\rho) \vec{q}_{VL} \quad (4.26)$$

for all  $\delta_l$ , except (when  $\zeta = 0$ ),  $\delta_l = \delta$ , and  $\delta_l = \delta - \Delta\psi$ . The vortex core factor  $\gamma_c(\rho)$  is given by Eq. 3.4.1 and  $\vec{q}_{VL}$  is given by Eq. A.24. The vortex core radius  $\rho_c$  is the same as that for airloads computations, including vortex core bursting. Since point  $P_\eta$  is in the wake, not on a rotor blade, the other close blade-vortex interaction effects do not apply.

The two tip vortex-line-segments adjacent to point  $P_\eta$  are represented by a single curved vortex-line-segment instead of two straight-line segments (Subsection 4.1.2). These segments are both shed from the same blade as point  $P_\eta$ ; i.e.,  $\zeta = 0$ , and have ages  $\delta_\ell = \delta$  and  $\delta_\ell = \delta - \Delta\psi$ . Recall from Subsection 1.5.2, that the age of a trailing vortex-line segment is defined as the age of its newer (smaller age, larger azimuth angle) end. Thus, points  $P_a$  and  $P_b$  for the single curved tip vortex-line segment are identified by  $(\phi, \delta_\ell)$  and  $(\phi - 2\Delta\psi, \delta_\ell + 2\Delta\psi)$ , respectively, where  $\delta_\ell = \delta - \Delta\psi$  and  $\phi = \psi + \zeta + \Delta\psi$ . The components of  $\vec{a}$  are computed using Eqs. 4.20, 4.22, and 4.24 directly. The components of  $\vec{b}$  are computed using Eqs. 4.21, 4.23, and 4.25, but with  $\Delta\psi$  replaced by  $2\Delta\psi$ . The vortex core radius  $\rho_c$  and circulation  $\gamma_a$  remain the same as for the straight-line-segment case. The  $\vec{q}$  contribution is equal to  $\vec{q}_{CVL}(\Delta\theta_a + \Delta\theta_b)$ , which is computed using Eq. C.37. The  $\vec{a}_c$  and  $\vec{b}_c$  of Appendix C are equal to  $\vec{a}$  and  $\vec{b}$ , respectively. Vortex-core effects are included in Eq. C.37.

For the single inboard trailing vortex line model,  $\gamma_a$  is computed using Subsection 2.8.1, and the vortex core radius is an input  $\rho_I$ . The components of  $\vec{a}$  and  $\vec{b}$  are computed using Eqs. 4.20 through 4.25 with  $\ell = \ell_2$  (Subsection 4.1.2). The contribution to  $\vec{q}$  is obtained from Eq. 4.26.

For the inboard trailing vortex sheet case,  $\vec{a}$  and  $\vec{b}$  are also computed using Eqs. 4.20 through 4.25 with  $\ell = \ell_2$ , and  $\gamma_a$  is defined in Subsection 2.8.1. No vortex core radius is used, but  $z_m$  and  $\Delta\tilde{x}$  are required (see Appendix B):

$$\Delta\tilde{x} = \ell_2 - \ell_1 \quad (4.27)$$

where  $\ell_1$  is the input root cutout, and

$$z_m = 0.5(z_a + z_b) \quad (4.28)$$

where  $z_a$  and  $z_b$  are evaluated for  $\ell = \ell_1$ , using Eqs. 4.24 and 4.25.

The contribution to  $\vec{q}$  is equal to  $\vec{q}_{VS}$ , which is computed using Eqs. B.22 or B.23, as necessary.

The  $n$  trailing-vortex-line case is not included in Subsection 2.8.1 so the computation of  $\gamma_a$  will be described here. Label the  $n_\ell = n$  trailing vortices  $\ell_\ell$ , where  $\ell_\ell$  runs from  $\ell_1$  at the root cutout to  $\ell_n = 1.0$  at the blade tip. Label the  $n_\eta = n - 1$  radial stations at which  $\gamma_{bv}(\eta_k, \phi)$  is known as  $\eta_k$ , where  $\eta_k$  runs from  $\eta_1$  between  $\ell_1$  and  $\ell_2$  to  $\eta_{n-1}$  between  $\ell_{n-1}$  and  $\ell_n$ . Let the circulation of the trailing vortex line  $\ell_\ell$  be  $\gamma_t(\ell_\ell, \phi)$ . Now at the root  $\ell_1$  and at the blade tip  $\ell_n = 1.0$ ,

$$\gamma_t(\ell_1, \phi) = -\gamma_{br}(\eta_1, \phi) \quad (4.28)$$

$$\gamma_t(1.0, \phi) = \gamma_{br}(\eta_{n-1}, \phi) \quad (4.29)$$

For all intermediate  $\ell_\ell$ ,

$$\gamma_t(\ell_\ell, \phi) = \gamma_{br}(\eta_{\ell-1}, \phi) - \gamma_{br}(\eta_\ell, \phi) \quad (4.30)$$

For all  $\ell_\ell$ , including  $\ell_n$ , the tip vortex,

$$\gamma_a = \gamma_t(\ell_\ell, \phi) \quad (4.31)$$

Finally, the contribution to  $\vec{q}$  is computed using Eq. 4.26.

Now, consider the shed-wake case. For this case,  $\vec{a}$  is the same as for the tip-vortex case and it is computed using Eqs. 4.20, 4.22, and 4.24. Point  $P_b$  is at the same azimuth  $\phi$  and age  $\delta_\ell$  as point  $P_a$ , but at a different  $\ell$ . Thus, the components of  $\vec{b}$  are also computed using Eqs. 4.20, 4.22, and 4.24, but with a different  $\ell$ . For the basic wake model with a single inboard trailing-vortex line, point  $P_a$  is at  $\ell_3$ , and point  $P_b$  is at  $\ell_2$ . If an inboard trailing-vortex sheet model is used together with a vortex-line-shed-wake model, point  $P_b$  moves to  $\ell_1$ . For the  $n$  trailing-vortex-line case, the shed-wake segment associated with  $\ell_\ell$  has

point  $P_a$  at  $\ell_\ell$  and point  $P_b$  at  $\ell_{\ell-1}$ . For all shed-vortex-line cases, the vortex-core radius is an input  $\rho_L$ . Normally  $\gamma_a$  and  $\gamma_b$  are equal to  $\gamma_s(\phi)$  from Eq. 2.9; however, when the inboard trailing vortex-sheet model is used, the shed-vortex-line circulation varies from  $\gamma_a = \gamma_s(\phi)$  to  $\gamma_b = 0.0$ . Finally, the contribution to  $\vec{q}$  is computed using Eq. 4.26 where  $\vec{q}_{VL}$  is obtained from Eq. A.23 or A.24, as necessary.

For the shed-vortex-sheet case there is always a segment having point  $P_a$  at  $\ell_3$  and point  $P_b$  at  $\ell_2$ . For this segment both  $\gamma_a$  and  $\gamma_b$  are equal to  $\gamma_s(\phi)$  from Eq. 2.9. There is no vortex-core radius but  $\Delta\tilde{x}$  and  $z_m$  are needed. To compute these parameters define  $\vec{a}_s$  and  $\vec{b}_s$  as  $\vec{a}$  and  $\vec{b}$ , now evaluated at  $\phi + \Delta\psi$  instead of  $\phi$  and  $\delta_\ell - \Delta\psi$  instead of  $\delta_\ell$ . Now,

$$\Delta\tilde{x} = 0.5(|\vec{a}_s - \vec{a}| + |\vec{b}_s - \vec{b}|) \quad (4.31)$$

$$z_m = 0.5(z_{as} + z_{bs}) \quad (4.32)$$

where  $z_{as}$  and  $z_{bs}$  are the  $\vec{k}(z)$  components of  $\vec{a}_s$  and  $\vec{b}_s$ , respectively. The contribution to  $\vec{q}$  is equal to  $\vec{q}_{VS}$  which is computed using Eq. B.23.

When an inboard trailing vortex-sheet model is used, there is a second shed-vortex-sheet segment. This segment has point  $P_a$  at  $\ell_2$  and  $P_b$  at  $\ell_1$ . The circulation varies from  $\gamma_a = \gamma_s(\phi)$  to  $\gamma_b = 0.0$ . The parameters  $\Delta\tilde{x}$  and  $z_m$  are obtained using Eq. 4.31 and 4.32 with the proper values of  $\ell$ . The contribution to  $\vec{q}$  is  $\vec{q}_{VS}$  computed using Eq. B.22.

The two shed vortex-sheet segments adjacent to point  $P_\eta$  are represented by one large segment to avoid the edge singularity (Subsection 4.2.1). These segments are both  $\zeta = 0$  and have ages  $\delta_\ell = \ell$  and  $\delta_\ell = \delta + \Delta\psi$ . Thus the single large segment has  $\vec{a}$  and  $\vec{b}$  defined at age  $\delta_\ell = \delta + \Delta\psi$  and azimuth angle  $\phi = \psi + \zeta - \Delta\psi$ , while  $a_s$  and  $b_s$  are defined at age  $\delta_\ell = \delta - \Delta\psi$  and azimuth angle

$\phi = \psi + \zeta + \Delta\psi$ . The rest of the computation proceeds like that for a normal shed-vortex-sheet segment.

#### 4.1.8 Bound Vorticity Contribution to Induced Velocity

Assuming lifting-line theory and steady-state blade motion, the net contribution of the bound vorticity to the induced velocity at points on the rotor blades is zero. Thus, the contribution of the bound vorticity to the induced velocity is neglected in airloads computations, except for the use of lifting-surface theory during a close blade-vortex interaction (Subsection 3.2.4). The bound vorticity cannot be neglected in distortion computations, however, because the induced velocity is computed at points in the wake.

Normally, the bound vorticity is represented by one or more vortex-line segments. These bound vortex-line segments can be thought of as the last of the set of shed-vortex-line segments. While the shed-vortex-line segments have ages  $\delta_\ell$  running from  $\delta + 2\pi M$  to  $\Delta\psi$  the age of the bound vorticity is always zero ( $\delta_\ell = 0$ ). The sign convention for  $\gamma_{bv}(\phi)$  is the opposite of the sign convention for  $\gamma_s(\phi)$ . Therefore points  $P_a$  and  $P_b$  are interchanged for the bound vorticity compared to the shed wake. Thus, point  $P_a$  is always inboard of point  $P_b$  in bound vorticity computations. Naturally,  $\gamma_a$  is equal to  $\gamma_{bv}(\phi)$  or  $\gamma_{bv}(\ell_\ell, \phi)$  as necessary. Keeping the differences listed here in mind, the contribution of the bound vorticity to the induced velocity ( $\Delta\vec{q}_{BV}$ ) is computed using the same techniques as for the corresponding shed-wake-vortex-line cases (Subsection 4.1.7).

While the technique outlined above is normally satisfactory, there is a problem when the bound vortex line passes near point  $P_\eta$ . The rotor blade is indexed in age in increments of  $\Delta\psi$  (typically  $\Delta\psi = 15^\circ$ ). When the rotor blade is close to point  $P_\eta$  a  $\Delta\psi$  change in the location of the blade can make a very large change in  $\Delta\vec{q}_{BV}$ .

Thus, sampling  $\Delta \vec{q}_{BV}$  at  $\Delta\psi$  intervals is not very accurate when the blade is close to point  $P_\eta$ .

The object of computing  $\Delta \vec{q}_{BV}$  is to ultimately find its contribution to the distortion  $\vec{D}(\psi, \delta)$ . Ideally, this should be done by integrating  $\Delta \vec{q}_{BV}$  over age  $\delta$ , as age goes from an initial value  $\delta - \Delta\psi$  to  $\delta$ ; thus obtaining the contribution to  $\vec{D}(\psi, \delta)$  directly. The program WG-71 is not able to compute  $\vec{D}(\psi, \delta)$  at this point, so the integrated  $\Delta \vec{q}_{BV}$  is divided by  $\Delta\psi$  to get an average value for  $\Delta \vec{q}_{BV}$  between ages  $\delta - \Delta\psi$  and  $\delta$ . Later this will be multiplied by  $\Delta\psi$  to get the increment to the distortion back again (Eq. 4.10).

Now recall that  $\delta_\lambda = 0$  for the bound vorticity. Thus, as age goes from  $\delta - \Delta\psi$  to  $\delta$  the azimuth angle  $\phi$  of the bound vortex line goes from  $\psi + \zeta + \delta - \Delta\psi$  to  $\psi + \zeta + \delta$ . Therefore, integrating  $\Delta \vec{q}_{BV}$  over age from  $\delta - \Delta\psi$  to  $\delta$  and dividing the result by  $\Delta\psi$  is the same mathematically (but not physically) as spreading the bound vortex line out into a vortex sheet running from  $\phi = \psi + \zeta + \delta - \Delta\psi$  to  $\phi = \psi + \zeta + \delta$ . This is convenient since it allows use of the vortex sheet formulas already built into WG-71. However, it is important to understand that the bound vortex line remains a line not a sheet. All that has been done is to integrate  $\Delta \vec{q}_{BV}$  over age  $\delta$  (which is equivalent to integration over azimuth angle  $\phi$  for this special case), and divide the result by  $\Delta\psi$  to obtain an average  $\Delta \vec{q}_{BV}$ .

The vectors  $\vec{a}$  and  $\vec{b}$  are the same as for a normal bound-vortex-line computation. To find  $\Delta \vec{x}$  and  $z_m$  define  $\vec{a}_{BV}$  and  $\vec{b}_{BV}$  as  $\vec{a}$  and  $\vec{b}$  evaluated for age  $\Delta\psi$  instead of zero and azimuth angle  $\psi + \zeta + \delta - \Delta\psi$  instead of  $\psi + \zeta + \delta$ . Now:

$$\Delta \vec{x} = 0.5 (|\vec{a}_{BV} - \vec{a}| + |\vec{b}_{BV} - \vec{b}|) \quad (4.33)$$

$$z_m = 0.5 (z_{aBV} + z_{bBV}) \quad (4.34)$$

where  $z_{aBV}$  and  $z_{bBV}$  are the  $\hat{k}(z)$  components of  $\hat{a}_{BV}$  and  $\hat{b}_{BV}$ , respectively. The induced velocity contribution  $\Delta\hat{q}_{BV}$  is equal to  $\hat{q}_{VS}$  computed using Eq. B.23.

The computation of this integrated  $\Delta\hat{q}_{BV}$  is much more expensive than the computation of the normal  $\Delta\hat{q}_{BV}$ . Fortunately, use of the integrated  $\Delta\hat{q}_{BV}$  is only important when the rotor blade passes near point  $P_\eta$  making  $\Delta\hat{q}_{BV}$  large. Therefore,  $\Delta\hat{q}_{BV}$  is always computed in the normal way. Then, if the resulting  $\Delta\hat{q}_{BV}$  is greater than an input QBM, the  $\Delta\hat{q}_{BV}$  is recomputed using the integration technique.

## 4.2 Distortion Computation Refinements

### 4.2.1 Near/Far Wake

Consider computing the contribution of a wake element to the induced velocity at point  $P_\eta$ . The farther away this wake element is from point  $P_\eta$  the less accuracy is required in specifying the geometry of the wake element relative to point  $P_\eta$ . This is because far wake elements make a smaller contribution to the induced velocity than near ones (assuming equal circulation), and because a given magnitude of error in the geometry will cause a percentage error in the geometry (and hence the induced velocity) which is smaller for far wake elements than for near ones. This suggests that the contribution of the far wake to the induced velocity at point  $P_\eta$  can be updated less often than the contribution of the near wake, without a significant loss in accuracy.

The basic near/far wake concept is that the contribution of each wake element to the induced velocity at each point  $P_\eta$  is computed at least once. After this initial computation, each wake element is assigned to either the near or the far wake, relative to each point  $P_\eta$ , based upon the magnitude of its contribution to the induced velocity. Any wake element whose contribution is greater than DM (an input to WG-71) becomes part of the near wake, while the rest of the wake becomes the far wake. Clearly, each

different point  $P_\eta$  will have a different near wake and far wake. A particular wake element can be part of the near wake for some points  $P_\eta$ , and part of the far wake for other points  $P_\eta$ .

The problem with this basic near/far wake scheme is the amount of core storage (fast access memory) required to store the induced velocity contribution of each wake element at each point  $P_\eta$ . First consider the number of different points  $P_\eta$ . This is the number of azimuth angle stations  $\psi$  (25 for  $\Delta\psi = 15^\circ$ ) times the number of age stations  $\delta$  (maximum of 97 in WG-71). This leads to 2425 points  $P_\eta$  which clearly leads to difficulties.

Consider the difference between  $\psi$  and  $\delta$ . At different azimuth angles  $\psi$  the whole pattern of the wake is different. At different ages  $\delta$ , with  $\psi$  held constant, the fundamental wake geometry remains fixed and only the distortion changes. Thus, those particular wake elements which compose the near wake and those which compose the far wake will change greatly as  $\psi$  changes, but will change very little as  $\delta$  changes. Therefore, a different near wake and far wake is provided for each point  $P_\eta$  having a different azimuth angle  $\psi$ , but the division of the wake into near and far wakes remains the same for all ages  $\delta$ . This provides nearly two orders-of-magnitude reduction in core storage (25 azimuth angles  $\psi$  instead of 2425 points  $P_\eta$ ).

This assumption that the near/far wake division is independent of age  $\delta$  is equivalent to saying that the near/far wake division is a function of age  $\delta_R$  measured from point  $P_\eta$ , not age  $\delta_\ell$  measured from the rotor. Consider a wake element associated with point  $P_\ell$ . Normally, point  $P_\ell$  is identified by  $(\ell, \phi, \delta_\ell)$  where  $\delta_\ell$  is age measured from the rotor. However, consider the problem of assigning point  $P_\ell$  to the near wake or to the far wake. It has been assumed that this assignment is independent of the age  $\delta$  of point  $P_\eta$ . This means that it is also independent of the position of the rotor, since this position will change as  $\delta$  changes. Since  $\delta_\ell$  is also measured from the position of the rotor, it is not

suitable for identifying point  $P_\ell$  in this case. Instead, the age of point  $P_\ell$  measured relative to point  $P_\eta$  is appropriate.

Define this relative age as

$$\delta_R = \delta_\ell - \delta \quad (4.35)$$

where  $\delta_R$  runs from  $2\pi M$  down to  $-\delta$  in steps of  $\Delta\psi$ . Notice that while  $\delta$  and  $\delta_\ell$  are both functions of the position of the rotor,  $\delta_R$  is not. To find the azimuth angle  $\phi$  of point  $P_\ell$ , substitute  $\delta_R$  into Eq. 4.3:

$$\phi = \psi + \zeta - \delta_R \quad (4.36)$$

Now the location of point  $P_\eta$  can be identified by  $(\ell, \phi, \delta_R)$  instead of  $(\ell, \phi, \delta_\ell)$ .

Although the near/far wake assignment of a wake element associated with a particular point  $P_\eta$  is independent of age  $\delta$ , the existence of the wake element is not. As an example of this, observe that the lower limit of  $\delta_R$  is  $-\delta$ . Thus, the contribution of either the near wake or the far wake to the induced velocity at point  $P_\eta$  will depend upon age  $\delta$  because the number of wake elements which actually exist depends upon  $\delta$ . This implies that two separate types of information must be stored:

- 1) the near/far wake assignment of each wake element relative to each azimuth angle  $\psi$ .
- 2) the total contribution of all far wake elements to the induced velocity at each point  $P_\eta$ .

The induced velocity contribution of the near wake does not require special storage provisions since it is recomputed every time it is needed.

The storage of the near/far wake assignments will be considered below, starting with the total number of wake elements. To store the far wake induced velocity contributions, define them as  $\vec{q}_F(\psi, \delta)$ . This has the same dimensions as  $\vec{D}(\psi, \delta)$  and requires the same amount of core storage (6.8k bytes in WG-71,

where one  $k$  is  $2^{10} = 1024$ ). As will be seen below, this 6.8k bytes storage penalty is a minor penalty for the two order of magnitude reduction in near/far wake assignment storage.

Now consider the number of different wake elements. At each relative age  $\delta_R$  there are  $n_\ell$  trailing wake elements (maximum of 6 in WG-71) plus  $n_\ell - 1$  shed wake elements. Now multiply this number by  $n_b$  blades (maximum of 6 in WG-71) and by the number of relative age  $\delta_R$  stations (average value 1.5 times the number of  $\delta$  stations). This product comes to 9603, and when further multiplied by 25 points  $P_\eta$  and 4 bytes per word requires about 940k bytes of core storage. For comparison, the entire WG-71 program requires 200 bytes, and when this program was originally developed, only about 400k bytes were available at MIT. Since then the amount of core storage available has increased by more than an order of magnitude; however, it is still costly.

Observe that when counting the number of wake elements, each point  $P_\ell$  was identified by  $(\ell, \zeta, \delta_R)$  instead of  $(\ell, \phi, \delta_R)$ . This is equivalent because  $\phi$  can be obtained from Eq. 4.36 given  $\psi$ ,  $\zeta$ , and  $\delta_R$ . The use of  $\zeta$  instead of  $\phi$  is desirable because there are normally fewer rotor blades (maximum of 6 in WG-71) than azimuth stations (25 for  $\Delta\psi = 15^\circ$ ). This suggests that attempts to reduce the number of  $\ell$  stations and the number of  $\delta_R$  stations may be profitable. First  $\ell$  will be considered.

For a given age relative  $\delta_R$  and rotor blade  $\zeta$  all of the wake elements at the different radial stations  $\ell$  are in the same general area. This suggests that all of these wake elements could be considered together as a unit. To do this, the contributions to the induced velocity at point  $P_\eta$  of all of these wake elements are added together. Then, if the total ( $\vec{q}_s$  in Fig. 25) is greater than DM, all of these wake elements are assigned to the near wake. Otherwise all of these elements become part of the

far wake. This eliminates  $l$  and reduces the core storage required by a factor of 11 in WG-71. However, this saving in core storage is purchased at the cost of some extra computational expense. This is because some wake elements included in the near wake under this scheme would not have been included if they had been considered separately.

Due to the reduction in the cost of core storage relative to the cost of computation since WG-71 was originally developed, the developer of a next generation distortion computation program should investigate considering each wake element separately. The core storage penalty for this could be reduced from the factor of 11 in WG-71 to a factor of 3 by eliminating the  $n$  trailing vortex-line-wake model and using only the basic wake model as in LDS-73.

Now consider the reduction of the number of  $\delta_R$  stations. It can be anticipated that a far wake element will tend to be adjacent to other far-wake elements more often than it is adjacent to near wake elements. Thus, as  $\delta_R$  changes with  $\zeta$  held constant there will be fewer transitions from far wake to near wake or from near wake to far wake than there are  $\delta_R$  stations. This suggests that, instead of storing the near/far wake assignments for each group of wake elements having the same  $\zeta$  and  $\delta_R$ , only the  $\delta_R$  at which these transitions occur needs to be stored.

Define the transition age  $\delta_T(\zeta, \psi, k)$  as the relative age  $\delta_R$  of the  $k$ 'th transition in the wake of the rotor blade identified by  $\zeta$ , relative to all points  $P_\eta$  having azimuth angle  $\psi$ . Large  $\delta_T(\zeta, \psi, k)$  are associated with small  $k$ . Assuming that the wake at  $\delta_R = 2\pi M$  will always be part of the far wake (if it is not,  $M$  is too small), then the first transition ( $k = 1$ ) will be from far wake to near wake. Therefore, odd values of  $k$  will always be associated with transitions from far wake to near wake, and even values of  $k$  will be associated with transitions from near wake to far wake.

In WG-71 there are provisions for a maximum of 16 different  $k$ . Therefore, the storage required for  $\delta_T(\zeta, \psi, k)$  is  $6\zeta$  times  $25\psi$  times 16  $k$  times 4 bytes per word which equals 9.4k bytes. The storage of  $\delta_T$  instead of  $\delta_R$  saves a factor of 9 in core storage and when combined with the factor of 11 saving due to summing over  $\ell$ , this is another two order of magnitude saving, from 940k bytes to 9.4k bytes.

Now consider the actual use of this near/far wake scheme in WG-71. For this program, the induced velocity contribution of the far wake is only computed once per iteration. However, both the near/far wake assignments and the induced velocity contribution of the far wake are computed separately for each iteration. A program which used continuous computation instead of iteration (see Subsection 4.1.4) would presumably also update the far wake at about  $2\pi m$  intervals in age.

To illustrate the details of using the near/far wake scheme, its application to the basic distortion iteration (Fig. 25) will be considered. The near/far wake scheme primarily affects the  $\delta_\ell$  loop, both at the start and at the finish. There are two basic cases to be considered:

- 1) The first time that the induced velocity contribution of a particular part of the wake is computed during the current iteration (for the basic distortion iteration this is whenever  $\delta = \delta_M$ ).
- 2) During an update.

First, consider case (1). The age  $\delta_\ell$  will be computed as in Fig. 25b, since the contribution of every wake element must be computed the first time through the wake. Now the usefulness of  $\vec{q}_s$  becomes clear. It is the sum over  $\ell$  of the induced velocity contributions of the wake of one blade having age  $\delta_\ell$ . Thus, if  $|\vec{q}_s| < DM$ , this wake is assigned to the far wake. This means that  $\vec{q}_s$  must be added to the far wake induced velocity contribution

$\vec{q}_F(\psi, \delta)$ , which will be considered in more detail below. It is also necessary to test for a transition.

To aid in finding the next transition, define  $k_m(\zeta, \psi)$  as the maximum value of the counter  $k$  in  $\delta_T(\zeta, \psi, k)$  which has been achieved at this point in the distortion iteration. At the start of the distortion iteration  $k_m(\zeta, \psi)$  is set equal to zero for all  $\zeta$  and  $\psi$ . Now if  $k_m(\zeta, \psi)$  is even, the last transition was from near wake to far wake. Since  $|\vec{q}_S| < DM$  implies another section of far wake, there is no transition. However, if  $k_m(\zeta, \psi)$  is odd, the last transition was from far wake to near wake. In this case,  $|\vec{q}_S| < DM$  implies a section of far wake and a transition from near wake to far wake. Therefore,  $k_m(\zeta, \psi)$  is incremented by one and using  $k$  equal to this new value of  $k_m(\zeta, \psi)$ :

$$\delta_T(\zeta, \psi, k) = \delta_\ell - \delta \quad (4.37)$$

Now consider the case  $|\vec{q}_S| > DM$ , which implies a near wake segment. In this case, odd  $k_m(\zeta, \psi)$  implies no transition. For even  $k_m(\zeta, \psi)$  there is a transition from far wake to near wake. Therefore,  $k_m(\zeta, \psi)$  is incremented by one and using  $k$  equal to this new value of  $k_m(\zeta, \psi)$ :

$$\delta_T(\zeta, \psi, k) = \delta_\ell - \delta + \Delta\psi \quad (4.38)$$

The transition age  $\delta_T(\zeta, \psi, k)$  is  $\Delta\psi$  larger than the relative age in this case. This is necessary because the trailing-wake segments identified by  $\delta_\ell$  actually extend from  $\delta_\ell$  to  $\delta_\ell + \Delta\psi$ .

In WG-71, the vectors from point  $P_\eta$  to the various points  $P_\ell$  ( $\vec{a}$  or  $\vec{b}$  as appropriate) are only computed for the current value of  $\delta_\ell$ . Thus, the  $\delta_\ell$  loop always starts with an initial  $\delta_\ell$  for which the vectors from point  $P_\eta$  to points  $P_\ell$  are computed but no induced velocities are computed. These vectors become the  $\vec{b}$  for the trailing-wake segments whose induced velocity contribution is computed at the second  $\delta_\ell$ . At the other end of the near-wake segment (Eq. 4.37), the extra  $\Delta\psi$  is not needed because this is

the last  $\delta_\ell$  for which the induced velocity contribution is computed.

The two-tip vortex-line segments adjacent to  $P_\eta$  are always part of the near wake even if their  $|\vec{q}_s|$  is less than DM. These are the two vortex-line segments which are combined into one curved vortex-line segment (Subsection 4.1.2). The relative ages  $\delta_R$  of these segments are zero and  $\Delta\psi$ . Thus, unless the segments at relative ages  $\delta_R$  of  $-\Delta\psi$  and  $2\Delta\psi$  are also part of the near wake, there will be a far wake to near wake transition (odd  $k$ ) for  $\zeta = 0$  and all  $\psi$  at  $\delta_T(0, \psi, k) = -\Delta\psi$  and a near wake to far wake transition (even  $k$ ) for  $\zeta = 0$  and all  $\psi$  at  $\delta_T(0, \psi, k) = \Delta\psi$ .

Now consider  $\vec{q}_F(\psi, \delta)$ . At the start of a distortion iteration  $\vec{q}_F(\psi, \Delta\psi)$  is set equal to zero. As the computation proceeds for  $\delta = \delta_M = \Delta\psi$  the appropriate  $\vec{q}_s$  are added to  $\vec{q}_F(\psi, \Delta\psi)$ . Next,  $\delta_M$  is incremented to  $2\Delta\psi$  and eventually  $\delta$  will equal  $2\Delta\psi$ . At this point, an initial value for  $\vec{q}_F(\psi, 2\Delta\psi)$  is needed. Now, all of the far wake elements which originally contributed to  $\vec{q}_F(\psi, \Delta\psi)$  are  $\Delta\psi$  older in age  $\delta_\ell$ , because the rotor has moved forward  $\Delta\psi$ . However, the relative age  $\delta_R$  of these wake elements has not changed. The basic assumption of the near/far wake scheme is that changes in the induced velocity contribution of far wake elements are neglected whether due to changes in age  $\delta_\ell$ , or due to an improved knowledge of the distortion. Thus,  $\vec{q}_F(\psi, 2\Delta\psi)$  is equal to  $\vec{q}_F(\psi, \Delta\psi)$  plus the  $\vec{q}_s$  of any new far-wake elements generated as the rotor moved forward by  $\Delta\psi$ . This can be generalized to say that the initial value of any  $\vec{q}_F(\psi, \delta)$  is the final value of  $\vec{q}_F(\psi, \delta - \Delta\psi)$ .

Now consider case (2), updating. In case (1), the transitions  $\delta_T(\zeta, \psi, k)$  and the far-wake induced velocities  $\vec{q}_F(\psi, \delta)$  were determined. In case (2), this information will be used. The use of  $\vec{q}_F(\psi, \delta)$  is clear. During any update  $\vec{q}_F(\psi, \delta)$  is added to  $\Sigma\vec{q}$ , representing the contribution of the far-wake elements, which are otherwise neglected by definition.

The use of  $\delta_T(\zeta, \psi, k)$  is to determine the ages  $\delta_\ell$  for which the induced velocity contribution will be updated (i.e., the near wake). Normally,  $\delta_\ell$  varies from  $\delta + 2\pi M$  to zero in steps of  $\Delta\psi$  (Fig. 25b). For this case,  $\delta_\ell$  varies in steps of  $\Delta\psi$  from  $\delta + \delta_T(\zeta, \psi, k)$  to  $\delta + \delta_T(\zeta, \psi, k+1)$  for all odd  $k$  from 1 up to either  $k_m(\zeta, \psi)$  or  $k_m(\zeta, \psi) - 1$  with the exception that any  $\delta_\ell < 0$  are neglected. This is because they represent wake elements which do not exist at the current value of  $\delta$ . Thus, the  $\delta_\ell$  values will come in several small groups instead of one big group.

This completes the description of the near/far wake scheme applied to the basic distortion iteration. Its application to WG-71 is very similar. The primary difference is that WG-71 does not employ complete updating all of the time. Thus, the criteria  $\delta < \delta_M$  is no longer sufficient to indicate updating (see Subsections 4.2.2 and 4.2.3). Another difference is that, when  $\delta_M = \Delta\psi$ , instead of using an odd or even  $k_m(\zeta, \psi)$  to determine the type of transition which last occurred, an indicator MGO is used. This is explained in the description of the actual distortion iteration (Subsection 4.2.5).

#### 4.2.2 Boundary Updating

The basic distortion iteration (Fig. 25) completely updates the computed  $\hat{D}(\psi, \delta)$  each time the boundary between the computed and the assumed wakes ( $\delta_M$ ) is incremented by  $\Delta\psi$ . This complete updating is very expensive. Therefore, consider the other extreme of no updating at all until the end of a complete iteration. This approach has been tried [18] and it proved to be unsuccessful. However, it is useful to start with no updating and then add more and more updating until an accurate and efficient distortion computation is achieved. This subsection will consider boundary updating while the next subsection will consider general updating, both of which are used in WG-71.

Consider what no updating implies. As mentioned in Subsection 4.1.5, it implies that the  $\delta$  loop (Fig. 25) is eliminated and that  $\delta$  is always equal to  $\delta_M$ . In addition to this, the  $\delta_\ell$  loop will no longer always run from  $\delta + 2\pi M$  to zero. For the first step ( $\delta_M = \Delta\psi$ ), the  $\delta_\ell$  loop will indeed run from  $\Delta\psi + 2\pi M$  to zero. However, for the next step ( $\delta_M = 2\Delta\psi$ ), the  $\delta_\ell$  loop will only run from  $\Delta\psi$  to zero. This is because the contribution to the induced velocity of all of the wake having age  $\delta_\ell$  between  $2\Delta\psi + 2\pi M$  and  $\Delta\psi$  has already been computed. Thus only the contribution of the new wake generated when the rotor was indexed from  $\delta_M = \Delta\psi$  to  $\delta_M = 2\Delta\psi$  needs to be computed.

This may be confusing. In the first step the contribution of the wake between  $\delta_\ell$  equal to  $\Delta\psi + 2\pi M$  and  $\delta_\ell$  equal to zero was computed. In the next step this same wake is referred to as running from a  $\delta_\ell$  of  $2\Delta\psi + 2\pi M$  to a  $\delta_\ell$  of  $\Delta\psi$ . This is because  $\delta_\ell$  is measured from the rotor and when the position of the rotor is advanced by  $\Delta\psi$  the  $\delta_\ell$  of any particular wake element is also increased by  $\Delta\psi$ .

Another way to look at this is to consider only where the wake is in relation to point  $P_\eta$  and to ignore the position of the rotor. The relative age  $\delta_R$  developed in Subsection 4.2.1 (Eq. 4.35) is the equivalent of  $\delta_\ell$ , but is measured from point  $P_\eta$  instead of from the rotor. Now in the first step the contribution of the wake running from a  $\delta_R$  of  $2\pi M$  to a  $\delta_R$  of  $\Delta\psi$  was computed. In the next step this wake is still labeled with the same values of  $\delta_R$  and the contribution of the new wake running from a  $\delta_R$  of  $\Delta\psi$  to a  $\delta_R$  of  $2\Delta\psi$  is computed. Thus, it is seen that no updating includes the assumption that the contribution to the induced velocity at point  $P_\eta$  of a wake element having a fixed relative age  $\delta_R$  does not change as the rotor advances, increasing both the age  $\delta$  of point  $P_\eta$  and the age  $\delta_\ell$  of the wake element.

Thus under the no updating assumption, the contribution of

the wake having any given relative age  $\delta_R$  is computed only once in a particular iteration. This implies that for any step where  $\delta_M$  (and hence  $\delta$ ) is incremented by  $\Delta\psi$  (except for the first step), the contribution of only that wake having  $\delta_\ell$  between  $\Delta\psi$  and zero and  $\delta_R$  between  $\delta - \Delta\psi$  and  $\delta$  is computed. This wake consists of the trailing-wake segments extending from  $\delta_\ell = 0$  to  $\delta_\ell = \Delta\psi$ , which are identified with  $\delta_\ell = 0$ , plus the shed wake at  $\delta_\ell = \Delta\psi$ . The contribution of the bound vorticity is also computed. The contribution of the rest of the wake is assumed to remain unchanged.

Now consider boundary updating. For this case, the age  $\delta$  remains equal to the boundary age  $\delta_M$  (hence, the name boundary updating). However, the assumption that the induced velocity at point  $P_\eta$  does not depend on the age  $\delta$  of point  $P_\eta$  is relaxed. This boundary updating only occurs at intervals of  $n_{DM}(\psi)$  steps  $\Delta\psi$  in the boundary age  $\delta_M$ , where  $n_{DM}(\psi)$  is an input to WG-71. Since only the distortion at the boundary  $\vec{D}(\psi, \delta_M)$  is affected by boundary updating, each azimuth angle  $\psi$  can be treated independently. This allows  $n_{DM}(\psi)$  to vary with  $\psi$  so that the wake along the sides of the rotor can be updated more often than the rest of the wake. This is desirable because the wake at the sides tends to distort more rapidly than the rest of the wake, due to the close proximity of the tip vortices from the various blades.

A distortion computation with only boundary updating is just like a computation with no updating until  $\delta_M$  reaches a value such that:

$$n_{DM}(\psi) = (\delta_M - \Delta\psi) / \Delta\psi \quad (4.39)$$

Then, at all azimuth angles  $\psi$  for which Eq. 4.39 holds, the induced velocity contribution of the near wake is updated (recomputed) for age  $\delta = \delta_M$ . After this the computation proceeds with no more updating at these  $\psi$  until:

$$2 n_{DM}(\psi) = (\delta_M - \Delta\psi) / \Delta\psi \quad (4.40)$$

Then the induced velocity contributions are updated again. This process continues with more updating at each integral multiple of  $n_{DM}(\psi)$ , until  $\delta_M$  equals  $2\pi m$  and an iteration is completed.

#### 4.2.3 General Updating

General updating is the only place in the distortion computation used by WG-71 where the age  $\delta$  is not required to be equal to the boundary age  $\delta_M$ . Clearly, when  $\delta$  is less than  $\delta_M$ , the computed  $\vec{D}(\psi, \delta)$  is an updated value. This is because there was another computation of this  $\vec{D}(\psi, \delta)$  earlier in the iteration when  $\delta_M$  was equal to this value of  $\delta$ . Thus general updating could also be called distortion updating. Similarly, boundary updating could also be called induced velocity updating, since a boundary update at a given  $\delta_M$  does not affect the distortion  $\vec{D}(\psi, \delta)$  for ages  $\delta$  less than  $\delta_M$ , where the distortion has already been computed.

General updating occurs every  $\ell_{DM}$  steps  $\Delta\psi$  in the boundary age  $\delta_M$ , where  $\ell_{DM}$  is an input to WG-71. The distortion computation proceeds like a distortion computation with boundary updating only (Subsection 4.2.2) until  $\delta_M$  reaches a value such that:

$$\ell_{DM} = (\delta_M - \Delta\psi) / \Delta\psi \quad (4.41)$$

At this point, a  $\delta$  loop is activated, like the  $\delta$  loop in Fig. 25a, where  $\delta$  runs from  $\Delta\psi$  to  $\delta_M$ . This causes the distortion  $\vec{D}(\psi, \delta)$  to be updated (recomputed) for all of these ages  $\delta$ .

Since it would be wasteful to use a more expensive distortion computation technique for updating than for the original computation, the boundary updating scheme is applied to this distortion updating process. Thus, when recomputing  $\vec{D}(\psi, \delta)$  for  $\delta$  between  $\Delta\psi$  and  $\delta_M$ , the boundary updating computational scheme (Subsection 4.2.2) is used, but with  $\delta_M$  replaced by  $(\delta_D + \Delta\psi)$  in Eqs. 4.39 and 4.40. It will be recalled that  $\delta_D$  is the boundary

age between the most recently updated distortion and the older distortion. It is necessary to add  $\Delta\psi$  to  $\delta_D$  to make it analogous to  $\delta_M$ , because  $\delta_D$  is the age of the most recently completed distortion computation, while  $\delta_M$  is the age for which the distortion is currently being computed, except during a general update.

The general updating interval  $\ell_{DM}$  is not a function of azimuth angle  $\psi$ , since the distortion  $\vec{D}(\psi, \delta)$  is being updated for all ages  $\delta$  from  $\Delta\psi$  to  $\delta_M$ . The accuracy of the updated  $\vec{D}(\psi, \delta)$  depends upon the  $\vec{D}(\phi, \delta_g)$  for all azimuth angles  $\phi$ , not just the  $\phi$  which happens to be equal to  $\psi$ . Thus it is important to update the distortion at all azimuth angles  $\psi$  simultaneously.

A word about the choice of the updating intervals  $n_{DM}(\psi)$  and  $\ell_{DM}$ . First they should always be chosen such that some integer times  $\Delta\psi$  times either  $n_{DM}(\psi)$  or  $\ell_{DM}$  will equal  $2\pi m$ . Thus, for  $\Delta\psi = 15^\circ$  and  $m = 2$ , the possible values of  $n_{DM}(\psi)$  and  $\ell_{DM}$  are 1, 2, 3, 4, 6, 8, 12, 16, 24, and 48. Also,  $\ell_{DM}$  should be an integral multiple of all values of  $n_{DM}(\psi)$ . Typically,  $n_{DM}(\psi)$  might have values of 3 and 6, depending on  $\psi$ , and  $\ell_{DM}$  might be 12.

#### 4.2.4 Averaging Incremental Distortion

For some cases the computed distortion shows a tendency to oscillate during the computation. The traditional cure for oscillations in an iterative computation is to average the results of successive iterations. This technique is used in WG-71. However, its application must be clearly thought out.

The obvious thing to do is to average the  $\vec{D}(\psi, \delta)$  from two successive distortion iterations and use this average  $\vec{D}(\psi, \delta)$  for the assumed distortion of the next iteration. This is not satisfactory, however, because general updating changes the value of  $\vec{D}(\psi, \delta)$  during an iteration. General updating can be also thought of as another distortion iteration within the main iteration. Therefore, instead of averaging the distortion from two successive iterations, the incremental distortion is averaged over

two successive computations.

This process is shown in the lower part of Fig. 26b. The old value of the distortion  $\vec{D}_0(\psi)$  is the same as it was for the basic distortion iteration (Fig. 25, Subsection 4.1.5). Just before  $\vec{D}_0(\psi)$  is set equal to  $\vec{D}(\psi, \delta)$ , the number stored in  $\vec{D}_0(\psi)$  will be the old value of  $\vec{D}(\psi, \delta - \Delta\psi)$ , except when  $\delta$  equals  $\Delta\psi$ . Thus the old value of the incremental distortion as age increases from  $\delta - \Delta\psi$  to  $\delta$  will be:

$$\Delta\vec{D}_0 = \vec{D}(\psi, \delta) - \vec{D}_0(\psi) \quad (4.42)$$

The current value of the incremental distortion is  $\Delta\psi\vec{q}_D(\psi)$ , as before. The weighted average of these two values is used to increment the computed distortion:

$$\vec{D}(\psi, \delta) = \vec{D}(\psi, \delta - \Delta\psi) + w_f \Delta\psi \vec{q}_D(\psi) + (1 - w_f) \Delta\vec{D}_0 \quad (4.43)$$

where  $w_f$  is an input weighting factor, normally 0.5. For the special case  $\delta = \Delta\psi$ , the distortion  $D(\psi, \delta - \Delta\psi)$  will always be zero. Thus

$$\Delta\vec{D}_0 = \vec{D}_0(\psi) = \vec{D}(\psi, \delta) \quad (4.44)$$

and

$$\vec{D}(\psi, \delta) = w_f \Delta\psi \vec{q}_D(\psi) + (1 - w_f) \vec{D}_0(\psi) \quad (4.45)$$

#### 4.2.5 Actual Distortion Iteration

The actual distortion iteration used in WG-71 includes the various refinements described in Subsections 4.2.1 through 4.2.4. A simplified flow chart for the actual distortion iteration is given in Fig. 26. This subsection will amplify the flow chart without repeating all of the details already covered.

Consider the indicator MGO, which is used to indicate the current state of the distortion iteration. There are four possible values for MGO: 0, 1, 2, and 3. When MGO is either 0 or 1, the boundary age  $\delta_M$  is equal to  $\Delta\psi$ . This is a special case because the contribution to the induced velocity of all of the wake between

the ages  $\delta_\lambda$  of  $2\pi M + \Delta\psi$  and zero is being computed for the first time in the current iteration. The tests for  $\delta_M = \Delta\psi$  shown in Fig. 26b are written as tests for  $MGO \leq 1$  in WG-71, because integer logic is faster. These values of MGO are also used to indicate the type of the last transition. For  $MGO = 0$ , the last transition was from far wake to near wake; i.e.,  $k_m(\zeta, \psi)$  odd. For  $MGO = 1$ , the last transition was from near wake to far wake; i.e.,  $k_m(\zeta, \psi)$  even. In WG-71 MGO is initially set equal to unity and  $k_m(\zeta, \psi)$  is set equal to zero.

The cases  $MGO = 2$  and  $MGO = 3$  contain no information about transitions. Instead they indicate the use of general updating (Subsection 4.2.3). When  $MGO = 2$ , a general update is in progress. A boundary update is also in progress if  $(\delta - \Delta\psi)/\Delta\psi$  is an integral multiple of  $n_{DM}(\psi)$ . When  $MGO = 3$ , the age  $\delta$  is equal to the boundary age  $\delta_M$ , and  $\Delta\psi$  of new wake has been generated. If  $(\delta_M - \Delta\psi)/\Delta\psi$  is an integral multiple of  $n_{DM}(\psi)$ , a boundary update will be in progress, but there is no general update as long as  $MGO = 3$ .

The flow chart in Fig. 26a consists of the  $\delta_M$  and  $\delta$  loops. The boundary age  $\delta_M$  loop is the same as in Fig. 25a. However, the age  $\delta$  loop is modified to provide for general updating. The loop runs from  $\delta_1$  to  $\delta_M$  instead of from  $\Delta\psi$  to  $\delta_M$ . The initial age  $\delta_1$  is  $\Delta\psi$  during a general update ( $MGO = 2$ ) and  $\delta_M$ , otherwise. The age  $\delta_s$  of the latest general update is used to test for the start of the next general update (Subsection 4.2.3). The induced velocity contribution  $\vec{q}_F(\psi, \delta)$  of the far wake is initialized to either zero (for  $\delta = \Delta\psi$ ), or  $\vec{q}_F(\psi, \delta - \Delta\psi)$ . Finally, the test for the end of an iteration is made on  $\delta_D$  instead of  $\delta_M$  to conform with WG-71. However,  $\delta_D$  will always be equal to  $\delta_M$  at that point in the computation so the result is the same.

The flow chart in Fig. 26b consists of the azimuth angle  $\psi$  loop and the distortion computation. A new variable  $\vec{q}_{TOT}(\psi)$  is

introduced which was not in the basic distortion iteration (Fig. 25a). This  $\vec{q}_{TOT}(\psi)$  contains the value of  $\Sigma \vec{q}$  at azimuth angle  $\psi$ , from the previous step in the age  $\delta$  loop. Thus, if  $\Sigma \vec{q}$  was written as a function of  $\psi$  and  $\delta$ , this  $\vec{q}_{TOT}(\psi)$  would equal  $\Sigma \vec{q}(\psi, \delta - \Delta\psi)$ . Unless a boundary update is in progress, or  $\delta_M = \Delta\psi$ , the initial value of  $\Sigma \vec{q}$  is:

$$\Sigma \vec{q}(\psi, \delta) = \vec{q}_{TOT}(\psi) = \Sigma \vec{q}(\psi, \delta - \Delta\psi) \quad (4.46)$$

since these induced velocity contributions are not recomputed (Subsection 4.2.2). The actual computation of the distortion  $\vec{D}(\psi, \delta)$  is modified to allow incremental distortion averaging (Subsection 4.2.4).

The flow chart in Fig. 26c corresponds to the basic distortion iteration flow chart in Fig. 25b. The details of initializing  $\delta_\ell$  and finding the next transition are not repeated here. They can be found in Subsection 4.2.1, or the listing of WG-71 (Appendix I) can be consulted. The initial value of  $\delta_\ell$  is stored in  $\delta_{ST}$  so that when  $\delta_\ell = \delta_{ST}$ , point  $P_\ell$  is located, but no induced velocities are computed. The details of finding transitions and adding  $\vec{q}_s$  to  $\vec{q}_F(\psi, \delta)$  are not repeated here. These details can be found in Subsection 4.2.1 or in the listing of WG-71 (Appendix I).

### 4.3 Hovering Wake Geometry

Since hovering is a special case of forward flight, it might be expected that a forward flight-wake geometry computation for  $\mu = 0$  would be satisfactory. This is not true, however. There is no relative wind in the hover case, so the wake does not move away from the rotor or from itself as fast as in the forward flight case. Thus, more wake must be included in the wake model which greatly increases the expense of the computation. There is a saving to compensate for this expense, however, since the hovering-wake geometry can be assumed to be axially symmetric. This eliminates the  $\psi$ -loop with a factor of  $(2\pi/\Delta\psi)$  saving in computational expense.

Ideally, a special hovering-wake-geometry program, with an associated hovering airloads program, should be developed. These programs should use a polar coordinate system to take full advantage of the axial symmetry. However, to evaluate the usefulness of the techniques developed in WG-71 for the hovering case, an optimum program is not required. Thus, a simple modification of WG-71 for the hovering case has been developed. This modification makes use of axial symmetry without converting the entire program to polar coordinates (Subsection 4.3.1), and it provides specialized wake models for the hovering case (Subsection 4.3.2).

A corresponding airloads computation has not been developed. The axial symmetry assumption means that the circulation is the same for all azimuth angles. The details of the radial variation of bound circulation are not needed when the basic wake model is used (Subsections 2.1 and 2.8). Thus, the circulation  $\gamma_0$  required for the hovering wake geometry computation is provided by hand computations using momentum/blade element theory [58].

#### 4.3.1 Axial Symmetry

Axial symmetry implies that the airloads and hence the circulation are the same at all azimuth angles  $\psi$ . It also implies that for any given radial station  $\eta$  and age  $\delta$  the wake geometry at point  $P_\eta$  will be the same for all  $\psi$ . Thus, it is necessary to compute the airloads and the wake geometry at only one value of  $\psi$ . This reduces the amount of computation required by a factor of  $(2\pi/\Delta\psi)$ .

While the tip vortex distortion and hence, the tip vortex geometry is computed for only one value of  $\psi$ , it is used at all azimuthal stations  $\phi$  when computing induced velocities. If the distortion were computed in polar coordinates  $(r, \theta, z)$ , this would be no problem, since the  $r, \theta$ , and  $z$  components of the distortion would be the same for all  $\phi$ . However, WG-71 is written in  $x, y, z$  coordinates and while the actual distortion vector does not change with  $\phi$ , its  $x$  and  $y$  components do change with  $\phi$ .

To maximize the use of the existing program WG-71, the x, y, z coordinate system is retained. The normal table of  $\vec{D}(\psi, \delta)$  is used and  $\vec{D}(\psi, \delta)$  is computed using  $\vec{q}_D(\psi)$  in the usual way (Fig. 26b). However, the main  $\psi$ -loop of Fig. 26b is executed for  $\psi = 0$  only. This gives a value for  $\vec{q}_D(0)$  only. To compute the rest of the  $\vec{q}_D(\psi)$ , define the x,y,z components of  $\vec{q}_D(\psi)$ :

$$\vec{q}_D(\psi) = q_{Dx}(\psi) \vec{i} + q_{Dy}(\psi) \vec{j} + q_{Dz}(\psi) \vec{k} \quad (4.47)$$

Now:

$$q_{Dx}(\psi) = q_{Dx}(0) \cos \psi + q_{Dy}(0) \sin \psi \quad (4.48)$$

$$q_{Dy}(\psi) = q_{Dy}(0) \cos \psi - q_{Dx}(0) \sin \psi \quad (4.49)$$

$$q_{Dz}(\psi) = q_{Dz}(0) \quad (4.50)$$

#### 4.3.2 Hovering Wake Models

The most important difference between forward flight-wake models and hovering-wake models is that a lot more wake is included in hovering-wake models. A  $\mu = 0.2$  distortion computation typically uses  $m = 2$  and  $M = 2$ , while a hovering-distortion computation typically uses  $m = 6$  and  $M = 12$ . Thus, the distortion is computed for the 6 turns ( $12\pi$  in age) of wake nearest the rotor, and the contribution to the induced velocity at point  $P_\eta$  of all wake elements within 12 turns ( $24\pi$  in age) of point  $P_\eta$  is computed. To reduce computation expense,  $\Delta\psi$  is normally doubled, from  $15^\circ$  to  $30^\circ$ .

In WG-71, all of the wake greater than  $2\pi M$  in age from point  $P_\eta$  is neglected. For the hovering case, this wake is represented by a semi-infinite vortex cylinder for each trailing vortex line (there is no shed wake in hovering due to the axial symmetry assumption). This cylinder is specified by point  $P_\ell$  on its upper edge. The radius of the cylinder is (when normalized by R):

$$r = 1 + D_{xy}(0, \delta_1) \quad (4.51)$$

where

$$\delta_1 = \delta + 2\pi M \quad (4.52)$$

Lamb [35] has shown that the velocity potential  $\Delta\phi_P$  at point P due to a closed vortex element of circulation  $\Gamma$  is:

$$\Delta\phi_P = \frac{\Gamma}{4\pi} \omega \quad (4.53)$$

where  $\omega$  is the solid angle subtended at P by the closed vortex element. Define  $\rho$  as the distance from the center of the vortex ring to point P (normalized by  $r$ ). Let  $x$  be the radial distance from the axis of the vortex ring to point P (normalized by  $r$ ) and  $z$  to be the distance from point P to the plane of the vortex ring (normalized by  $r$ ). Now

$$\rho = \sqrt{x^2 + z^2} \quad (4.54)$$

To define the solid angle  $\omega$ , consider a sphere of radius  $\rho$  centered at point P, and a conical surface connecting the vortex ring and point P. Let A be the area on the surface of the sphere which is surrounded by the intersection of the sphere and the conical surface. When

$$\omega = A / \rho^2 \quad (4.55)$$

Now, if  $\rho$  is so large that the curvature of the surface of the sphere in area A can be neglected, the area A can be approximated by a planar ellipse of minor axis  $r(z/\rho)$  and major axis  $r$ . Normalizing A by  $r^2$ :

$$A \approx \pi z / \rho \quad (4.56)$$

Therefore

$$\omega \approx \pi z / \rho^3 \quad (4.57)$$

This leads to an approximation for the velocity potential

$$\Delta\phi_p \approx \frac{\Gamma}{4} \frac{z}{(x^2 + z^2)^{3/2}} \quad (4.58)$$

Now consider a semi-infinite vortex cylinder extending from  $z$  to  $\infty$ . This cylinder is made up of an infinite number of vortex rings, each having circulation  $d\Gamma/dz$ . Therefore, the velocity potential of this cylinder at point P is

$$\phi_p = \frac{1}{4} \frac{d\Gamma}{dz} \int_z^{\infty} \frac{z dz}{(x^2 + z^2)^{3/2}} = \frac{1}{4} \frac{d\Gamma}{dz} \left( \frac{1}{\sqrt{x^2 + z^2}} \right) \quad (4.59)$$

The  $x$  and  $z$  components of the induced velocity at point P are

$$q'_{px} = \frac{1}{rR} \frac{\partial \phi_p}{\partial x} = \frac{-1}{4rR} \frac{d\Gamma}{dz} \frac{x}{(x^2 + z^2)^{3/2}} \quad (4.60)$$

$$q'_{pz} = \frac{-1}{rR} \frac{\partial \phi_p}{\partial z} = \frac{1}{4rR} \frac{d\Gamma}{dz} \frac{z}{(x^2 + z^2)^{3/2}} \quad (4.61)$$

where the signs are chosen in accordance with the conventions of WG-71.

To calculate  $d\Gamma/dz$ , observe that circulation  $n_b \Gamma$  ( $n_b$  = number of blades) will accumulate as the rotor turns  $2\pi$  in azimuth. During the same time, the wake will move downwards at velocity  $\lambda \Omega R$  an amount

$$rR z = \frac{2\pi}{\Omega} \lambda \Omega R \quad (4.62)$$

Therefore

$$\frac{1}{rR} \frac{d\Gamma}{dz} = \frac{n_b \Gamma}{2\pi \lambda R} \quad (4.63)$$

Now using

$$T = \frac{1}{2} n_b \rho \Omega R \Gamma R \quad (4.64)$$

$$C_T = \frac{T}{\rho \pi R^2 (\Omega R)^2} \quad (4.65)$$

$$\lambda = \sqrt{C_T/2} \quad (4.66)$$

It can be shown that

$$\frac{1}{rR} \frac{d\Gamma}{dz} = 2\lambda \Omega R \quad (4.67)$$

Normalizing the x and z components of the induced velocity with the tip speed  $\Omega R$  and using Eq. 4.67:

$$g_{Px} = -\frac{\lambda}{2} \frac{x}{(x^2 + z^2)^{3/2}} \quad (4.68)$$

$$g_{Pz} = \frac{\lambda}{2} \frac{z}{(x^2 + z^2)^{3/2}} \quad (4.69)$$

Now expressions for x and z are needed. The vortex rings are assumed to be parallel to the TPP. Define the  $x_p$  and  $y_p$  as the  $\hat{i}$  and  $\hat{j}$  components of a vector, parallel to the TPP, which goes from the axis of the vortex cylinder to point P (point  $P_\eta$  in the notation of WG-71).

$$x_p = D_{\eta x}(0, \delta) \quad (4.70)$$

$$y_p = \eta + D_{\eta y}(0, \delta) \quad (4.71)$$

The magnitude of this vector is rx.

$$x = \sqrt{x_p^2 + y_p^2} / r \quad (4.72)$$

Now z is the vertical (k) component of the vector from point  $P_\eta$  to point  $P_\ell$ :

$$z = \frac{1}{r} \left[ \mu \tan i (\delta_\ell - \delta) - a_o (1 - \eta) + D_{\ell z}(0, \delta_\ell) - D_{\eta z}(0, \delta) \right] \quad (4.73)$$

where  $\delta_\ell$  is given by Eq. 4.52.

Finally, the  $\hat{i}, \hat{j}, \hat{k}(x, y, z)$  components of the induced velocity contribution  $\vec{q}$  of the vortex cylinder are

$$\gamma_x = \gamma_{px} \left( x_p / \sqrt{x_p^2 + y_p^2} \right) \quad (4.74)$$

$$\gamma_y = \gamma_{py} \left( y_p / \sqrt{x_p^2 + y_p^2} \right) \quad (4.75)$$

$$\gamma_z = \gamma_{pz} \quad (4.76)$$

The hovering-wake geometry computation computes the tip vortex distortion only. Therefore, the geometry of the inboard trailing wake is normally determined by the rigid wake assumption (Subsection 1.5.1). However, Landgrebe [23] has developed an empirical wake geometry correlation for both the tip vortex and the inboard trailing wake. This correlation shows that the inboard trailing wake is a vortex sheet whose vertical velocity is much smaller near the root than near the tip. A set of formulas are given in [23] for the geometry of this inboard vortex sheet. These formulas have been included as an option in the hovering wake geometry computation when an inboard trailing-vortex sheet model is used.

## SECTION 5

### RESULTS AND CONCLUSIONS

The results presented here consist of top and side views of the tip vortex geometry (for example, Fig. 1) and of plots of airloads (lb/in) vs. azimuth angle  $\psi$  at a given radial station  $r$  (for example, Fig. 2). These results are compared with measured data from experiments when such data are available. The calculated tip vortex geometry is also compared with the classical rigid wake tip vortex geometry (see Subsection 1.5.1). Unfortunately, there is no case where experimental data is available for both tip vortex geometry and airloads.

The results are primarily designed to show the effects of the various models and of computational parameters on both tip vortex geometry and airloads. The results presented here are restricted to those obtained using the final versions of the airloads program LDS-73 and the wake geometry program WG-71 as listed in Appendices F and I. Thus, anyone using these programs should be able to duplicate these results. These programs and their predecessors have been continuously developed and modified over the past ten years. It was not financially practical to repeat all of the cases previously run, using these older programs. Furthermore, some wake models which were evaluated on older programs have been eliminated from the current programs to save computer memory space (core storage). Thus, these older results will be mentioned occasionally in cases where the modifications to the programs involved do not significantly affect the point in question.

Both airloads and tip vortex geometry have been computed at various times for one, two, three, four, and six bladed rotors at various advance ratios from zero to 0.45. The results presented here are restricted to four- and six-bladed rotor airloads, with

the corresponding tip vortex geometries, plus a one-blade tip vortex geometry case (for comparison with smoke tests). These results are representative of all of those obtained at low to moderate advance ratios ( $\mu = 0.1$  to  $0.3$ ). Due to the neglect of torsional motion in the blade motion solution the airloads program is not suitable for high advance ratios. Hover ( $\mu = 0$ ) is treated as a special case (see Subsection 4.3).

Most of the results presented are for the four-blade case with advance ratio  $\mu = 0.18$ . This has been the standard airloads case for many years and a large background of computational experience has been developed. A standard set of inputs (i.e., wake model plus computational parameters) has been developed for this case, which is designed to give good agreement with the measured data at reasonable expense. The effects of changing the various input parameters are demonstrated by permutations from this standard set of inputs. This same standard set of inputs has been tested on other cases (such as the six-blade case) to ensure that it is not too specialized.

The largest and most important airloads occur on the outer portion of the rotor. Thus, the radial stations chosen are more closely spaced outboard and the results presented are normally for the outboard radial stations. It is not necessary to present the airloads results from all six radial stations for each permutation of the inputs. Instead the airloads results are normally presented for only one of three outboard radial stations, unless there is a significant difference between the results at the various radial stations. The radial station chosen is varied so that examples of results from all of the outboard radial stations are shown. Results from inboard radial stations are shown only when they are of special interest.

The tip vortex geometry plots show the geometry of the tip vortex from one blade at the instant when that blade is at azimuth angle  $\psi_s$ . The geometry will be different for each

different  $\psi_s$ , because the age  $\delta$  of the various points  $P_\eta$  in the wake is changed by changing  $\psi_s$ . However, the changes with increasing age are normally slow enough so that results at one or two values of  $\psi_s$  (normally  $\psi_s = 180^\circ$  or  $0^\circ$ ) are enough to show the wake behavior.

### 5.1 Wake Model Parameters

This subsection considers the effects of variations in the wake model on the results. Only those wake model parameters which apply to both wake geometry and airloads computations will be considered. More specialized wake model parameters will be considered later (Subsections 5.2 and 5.3). The results presented are mostly rigid wake airloads for the four-blade,  $\mu = 0.18$  case (Table 2). However, these wake model parameters have also been tested for various other cases for both airloads and wake geometry, using the older versions of the programs LDS-73 and WG-71.

Consider  $\Delta\phi$ , the azimuthal extent of the straight trailing vortex line and vortex sheet segments used in the wake model. Rigid wake airloads were computed for  $\Delta\psi = 15^\circ$  with  $\Delta\psi = 15^\circ, 30^\circ$ , and  $45^\circ$ . The results at  $\eta = 0.85$  are typical and Fig. 27 shows those for  $\Delta\phi = 15^\circ$  and  $30^\circ$ , compared with measured flight test data [49]. The results for  $\Delta\phi = 45^\circ$  are not presented, but they show even larger differences from the  $\Delta\phi = 15^\circ$  results. The current programs LDS-73 and WG-71 cannot be used with  $\Delta\phi$  less than  $15^\circ$ . However, older versions of both programs have been run with  $\Delta\phi = 7.5^\circ$ . The results were very similar to those with  $\Delta\phi = 15^\circ$ , for rigid wake cases. For distorted wake cases, some extra bumps in the tip vortex were picked up but the overall pattern remained the same. Thus, the distorted wake airloads for  $\Delta\phi = 7.5^\circ$  were very similar to those for  $\Delta\phi = 15^\circ$ .

It is concluded that  $\Delta\phi = 15^\circ$  is satisfactory for rigid wake airloads computations and for the computation of the gross tip vortex distortion. For the details of the tip vortex

distortion very near a rotor blade, or another tip vortex, very small  $\Delta\phi$ , much less than one degree, would be required. This is clearly impractical for an overall computation of the entire wake, as considered here. Any computations of local tip vortex distortion should be done as a separate problem isolated from the computation of the rest of the wake. For cases where the expense of computation must be reduced even at some cost in accuracy, a rigid wake computation with  $\Delta\phi = 30^\circ$  is suggested (see Fig. 27). However,  $\Delta\psi = 15^\circ$  should be retained, or peaks in the airloads may be lost.

The azimuthal extent of the wake included in airloads computations is  $2\pi m$ . Normally,  $m$  is 4 at  $\mu = 0.10$ , 3 at  $\mu = 0.15$ , and 2 at  $\mu = 0.20$ . To test the effect of  $m$ , rigid wake airloads were computed for a four-blade rotor at  $\mu = 0.18$  with  $m = 1, 2$ , and 3. The results for  $m = 1$  and  $m = 2$  are shown in Fig. 28 at  $\eta = 0.95$ . The results for  $m = 3$  coincide with the  $m = 2$  curve. A set of distorted tip vortex airloads for  $m = 2$  and  $m = 3$  was also computed for this case. Again, the results were practically identical. Runs made with the older versions of LDS-73 and WG-71 with  $M = m$  for various advance ratios confirm these results. Thus,  $m = 0.4/\mu$  is the suggested criterion for  $m$ , with hover ( $\mu=0$ ) being a special case (Subsection 4.3.2).

Now consider the inboard trailing wake. Rigid wake airloads were computed with, and without, the inboard trailing wake for the four-blade,  $\mu = 0.18$  case. At the outer two radial stations there is some difference, while at the 75% radius (Fig. 6) and inboard there is a marked difference, especially at  $\psi = 0$ . Wake geometry computations made using the older version of WG-71 confirm this. Thus, the inboard trailing wake should not be neglected. This leaves the question of how to model it. The n-trailing-vortex-line model (Subsection 2.2) is not available in the current LDS-73; however, runs made for  $n = 6, 10$ , and 20 with an older version of LDS-73 showed very similar results at outboard

radial stations ( $\eta > .7$ ) when compared with the basic wake model (Subsection 2.1). A similar comparison was made with an older version of WG-71 with similar results. This comparison has not been repeated using the current WG-71 due to the great expense involved.

The basic wake model has provision for either a large-core vortex line model or a vortex sheet model of the inboard trailing wake (Subsection 2.6). Rigid-wake airloads were computed using these two options for a four-blade,  $\mu = 0.18$  case. The results at the outer three radial stations are very similar, but from  $\eta = 0.55$  (Fig. 29) inboard the large-core vortex line model shows better agreement with the measured flight test data [49] near  $\psi = 0$ . This is surprising, since the vortex sheet model was expected to be closer to reality.

To check this result, rigid-wake airloads were computed for the six-blade,  $\mu = 0.108$  case (Table 2) using both models. There is no measured data at  $\eta = 0.55$ , but the  $\eta = 0.40$  station shows the same behavior near  $\psi = 0$  as the four-blade case, with the vortex sheet model predicting very large airloads while the large-core vortex line model agrees with the measured data [51]. A tip vortex geometry computation was also run, using the vortex sheet model, for the four-blade,  $\mu = 0.18$  case. The results for  $\psi_s = 0^\circ$  (Fig. 30b) are compared with the large-core vortex line model results (Fig. 30a). The large bump in vortex sheet model geometry near  $\psi = 180^\circ$  can be traced to the influence of the vortex sheet inboard trailing wake.

To test the sensitivity of these results to the vortex sheet vortex core radius  $\rho_{vs}$ , values of  $\rho_{vs}$  as large as 0.050 (compared to the normal value of 0.0025) were tried for the four blade,  $\mu = 0.18$  case. The details of the airloads results changed but the error near  $\psi = 0^\circ$  at the inboard radial stations remained. Thus, it is concluded that the inboard trailing wake partially rolls up so that its circulation distribution is more

nearly circular than planar. This is not to say that it rolls up into a tight, concentrated vortex similar to the tip vortex, because the use of a small-core vortex line model leads to large airloads peaks at the inboard radial stations which do not appear in the measured data.

Now consider the shed wake. Rigid wake airloads were computed for the four-blade,  $\mu = 0.18$  case: with no shed wake, with near shed wake only, and with both near- and far-shed wake. The results show that the far-shed wake has almost no effect for this case and that the near-shed wake effect is small. The tip vortex distortion was also computed for this case with and without shed wake (there is no near-shed wake in a distortion computation). The distortion results were not changed by the shed wake. Finally, rigid-wake airloads were computed for the six-blade,  $\mu = 0.108$  case (Table 2), with and without shed wake. The shed-wake effect on the results is larger for this six-blade case than for the four-blade case. These six-blade airloads results are plotted at the 85% radius in Fig. 31, including some measured flight-test data [51].

These results were obtained using the large-core vortex-line far-shed-wake model and the vortex sheet near-shed-wake model (Subsection 2.7). Previous results from older versions of LDS-73 and WG-71, which used a small core vortex line shed-wake-model, showed much larger shed-wake effects. It is now thought that these larger effects were due to spurious peaks in the induced velocity due to the use of the small-core vortex-line shed-wake-model. Thus it is concluded that the far-shed wake can be safely neglected, which will save some computational expense.

The near-shed wake is another matter. To understand the larger near-shed-wake effects in the six-blade case compared to the four-blade case, consider their reduced frequencies:

$$k = \frac{\omega b}{V} = \frac{\omega b}{\Omega R} \quad (5.1)$$

where  $\omega$  is the predominant frequency of the harmonic airloads. The semi-chord to radius ratio ( $b/R$ ) is about the same for both cases (.025 and .030), but the frequency ratio of the harmonic airloads ( $\omega/\Omega$ ) is not. In the four-blade case, the first, second, and third harmonics predominate. Taking the second harmonic as typical, the reduced frequency  $k$  becomes 0.050. In the six-blade case, the first, second, third, fifth, and seventh harmonics are all important. Taking the third harmonic as typical,  $k$  becomes 0.090. Miller [9] has developed an approximate expression for the two-dimensional lift deficiency function  $F$  when  $k$  is less than 0.5 which agrees well with Theodorsen:

$$F = \frac{1}{1 + k(\pi/2)} \quad (5.2)$$

This gives values of  $F$  of 0.93 and 0.875 for the four-blade and the six-blade cases, respectively. The shed-wake effect shown in Fig. 31 seems to agree with this estimate of  $F$ .

## 5.2 Wake Geometry Results

### 5.2.1 Computational Parameters

The computational parameters are the near/far wake parameter  $DM$  and the updating parameters  $\ell_{DM}$  and  $n_{DM}(\psi)$ , see Subsection 4.2. The values for these parameters were determined by making a series of runs with decreasing values of the parameters until further decreases no longer had a significant affect on the results. A total of fourteen runs were made, using an older version of WG-71, for the one blade,  $\mu = 0.10$  case (Table 2). The results of this study were that  $DM$  should be less than ten percent of the induced downwash ( $\lambda - \tan i$ ) and that  $\ell_{DM} = 12$  together with  $n_{DM}(\psi) = 3$  along the sides of the rotor and  $n_{DM}(\psi) = 6$  elsewhere are satisfactory.

To make sure that these results are still valid for the current version of WG-71 several runs were made for the four blade,  $\mu = 0.18$  case. For the standard set of inputs  $DM = 0.0020$ ,  $\ell_{DM} = 12$ ,  $n_{DM}(\psi) = 3$  (from  $\psi = 45^\circ$  to  $135^\circ$  and from  $\psi = 240^\circ$  to  $330^\circ$ )

and  $n_{DM}(\psi) = 6$  elsewhere. The tip vortex geometry obtained using these inputs is shown in Fig. 1 ( $\psi_s = 180^\circ$ ) and Fig. 30a ( $\psi_s = 0^\circ$ ). Runs were made for  $DM = 0.0010$  and  $DM = 0.0005$  together with the standard values of  $\ell_{DM}$  and  $n_{DM}(\psi)$ . The results were essentially the same as those for  $DM = 0.0020$ . The  $DM = 0.0005$  results are shown in Fig. 32 for  $\psi_s = 180^\circ$ . Another run was made with  $DM = 0.0020$ ,  $\ell_{DM} = 4$ , and  $n_{DM}(\psi) = 2$  (for all  $\psi$ ). These results are shown in Fig. 33 for  $\psi_s = 180^\circ$ . Comparing Fig. 33 with Fig. 1, there are some small differences; however, they are in areas far from the rotor and hence are not important in airloads computations. Thus, it is concluded that the standard values of  $DM$ ,  $\ell_{DM}$ , and  $n_{DM}(\psi)$  are small enough to give satisfactory results.

A comparison of the execution times required for WG-71 using various values of  $DM$ ,  $\ell_{DM}$ , and  $n_{DM}(\psi)$  is given in Table 3. The execution time for the corresponding airloads computation using LDS-73 is also given. While the exact times are very dependent on the computer used (see Table 3), the relationship between the airloads computation and the wake geometry computation is not. It is estimated that a four-blade,  $\mu = 0.18$  case with  $DM = 0.002$ ,  $\ell_{DM} = 1$ , and  $n_{DM}(\psi) = 1$  (i.e., complete updating) would require 400 to 500 seconds. A similar case without the near/far wake approximation (i.e.,  $DM = 0.0$ ) might require 5000 to 10000 seconds.

### 5.2.2 Comparison with Smoke Data

Qualitative experimental data on the tip-vortex geometry in forward flight is available from smoke tests and water tunnel tests. However, there is a lack of accurate quantitative data. Thus, the accuracy of the wake-geometry computation can only be evaluated qualitatively by comparison with these smoke tests or indirectly through airloads computations. The indirect technique does not work because of the current poor understanding of close blade-tip vortex interactions. Thus, we are left with a qualitative evaluation.

The clearest smoke pictures available are the culmination of several years of part-time work by John Thompson, F.S. Stoddard, M.W. Hurst, and Gregg Erickson. The experimental apparatus and technique are described by Erickson [59]. The results used here were taken by Erickson after his 16.62 project [59] was completed. The case chosen is a one-blade case at  $\mu = 0.10$ . Both two- and four-blade cases were also run at advance ratios up to 0.3; however, the one-blade photographs are the clearest. This is because the wake of the extra blades and the blades themselves interact with the visualized tip vortex (i.e., the one with smoke injection), causing the smoke to disperse in places.

Photographs of the smoke were taken simultaneously from the side and from the bottom. An attempt was made to reduce these simultaneous photographs to quantitative wake-geometry data. However, the reduced results did not make sense. The length of the rotor blade came out wrong, for example, and extra bumps appeared in the reduced data which did not appear in the photographs. It was concluded that the location of the side camera might have been in error, which would explain the problem.

The tip vortex geometry was computed for this one blade,  $\mu = 0.10$  case (Table 2). The results are compared with some partially reduced smoke data in Fig. 34a ( $\psi_s = 0^\circ$ ) and Fig. 34b ( $\psi_s = 180^\circ$ ). Only the side view is shown and to clarify the presentation, the far side of the wake ( $\psi = 0^\circ$  to  $180^\circ$ ) is dashed. It is believed that the lower location of the far side of the wake in the smoke data compared to the computed data is partially due to an error in the vertical location of the side camera. Otherwise there is good qualitative agreement. Similar comparisons have been made for both two- and four-blade cases using an older version of WG-71 and the qualitative agreement is also good, although there are some gaps in the smoke data due to dispersion of the smoke as described above.

The side photograph corresponding to Fig. 34b is shown in Fig. 35. The corresponding bottom photograph is not shown because it was taken through a fish-eye lens which caused confusing distortion. The complete computed tip vortex geometry corresponding to Figs. 34a and 34b is shown in Fig. 36a ( $\psi_s = 180^\circ$ ) and Fig. 36b ( $\psi_s = 0^\circ$ ).

### 5.2.3 Other Forward Flight Results

All of the wake-geometry results presented here are computed using circulation distributions computed by LDS-73 for a rigid wake. To test the validity of this, a wake geometry computation was made for the four-blade,  $\mu = 0.18$  case using a circulation distribution computed by LDS-73 for the tip vortex distortion shown in Figs. 1 and 30a. The results were identical with those in Figs. 1 and 30a. For a comparison of the airloads associated with these two circulation distributions (i.e., rigid wake and distorted wake) see Fig. 2.

As an example of the computed tip vortex geometry of a different case, the six-blade,  $\mu = 0.108$  case was run. The results are presented in Figs. 37a ( $\psi_s = 180^\circ$ ) and 37b ( $\psi_s = 0^\circ$ ). The tip vortex geometry far downstream ( $y$  greater than 3.5) may not be very accurate since the location of much of the wake which contributes to the induced velocity in that region is extrapolated. However, this is not important, since that part of the wake is too far away from the rotor to significantly affect airloads. A comparison of rigid vs. distorted wake airloads for this case will be shown in Subsection 5.3.

### 5.2.4 Discussion of Forward Flight Results

The most important result of these tip-vortex-geometry computations is that, over the forward portion of the rotor, the tip vortex tends to stay in the tip-path plane until the tip vortex from the next blade comes by to push it down (see Figs. 1 and 37a). This result has important consequences in airloads

computations (Subsection 5.3). This subsection will consider the physics behind this important result.

The circulation of the tip vortex is such that it induces downwash on its concave side and upwash on its convex side when viewed from the top. Consider the tip vortex of the  $\psi = 180^\circ$  blade of a four-blade rotor at  $\mu = 0.18$  (Fig. 1). Between  $\psi = 180^\circ$  and  $\psi = 105^\circ$ , this tip vortex is the outermost in a nest of tip vortices from the various blades. Thus, it experiences an induced upwash from these other tip vortices. It will also experience an induced downwash from the inboard trailing wakes of these blades, but this is smaller because the wake which induces it is farther away. Thus, there is a net induced upwash on the tip vortex in this region. At about  $\psi = 105^\circ$  on the tip vortex, the  $\psi = 90^\circ$  blade comes by (the vertical line from the hub in Fig. 1). The tip vortex from this  $\psi = 90^\circ$  blade is outboard of the tip vortex from the  $\psi = 180^\circ$  blade and hence induces a large downwash. However, a new source of upwash delays the effect of this downwash  $15^\circ$ , as discussed below.

There is a similar situation in the six-blade,  $\mu = 0.108$  case (Fig. 37a). In this case, the next blade is at  $\psi = 120^\circ$  instead of at  $\psi = 90^\circ$  and its tip vortex pushes the tip vortex of the  $\psi = 180^\circ$  blade down at  $\psi = 120^\circ$  and at  $\psi = 105^\circ$ . However, observe that the returning part of the tip vortex of the  $\psi = 180^\circ$  blade is inducing upwash on itself at  $\psi = 90^\circ$ . This, together with upwash induced by similar returning tip vortices from the other blades, causes the tip vortex of the  $\psi = 180^\circ$  blade to go back up at  $\psi = 90^\circ$ . A similar, but less intense, effect is also present in the four-blade,  $\mu = 0.18$  case, causing the  $\psi = 90^\circ$  point to remain in the tip-path plane.

In summary, there is a sound physical explanation for the behavior of the tip vortex over the forward portion of the rotor, which clearly indicates that the tip vortex should be closer to the tip-path plane than the rigid-wake model would suggest.

#### 5.2.5 Hovering Results

The hovering wake geometry program has not been modified to include the latest modifications to WG-71. Thus, only old results from 1971 and 1972 are available. The last runs made were for comparison with some smoke-test data by Landgrebe [23]. The results are shown in Fig. 38. The computed geometry does not contract rapidly enough near the rotor and hence does not go down fast enough either. This is true of Landgrebe's computations [23] also. It is thought that this discrepancy is due to a lack of understanding of the details of the formation and roll-up of the tip vortex very near the blade. The vortex sheet plus the vortex line (VSUL) tip-vortex model (Subsection 2.5.3) was not used in these computations; however, it is probably too crude to solve this problem in any case.

When the hovering wake-geometry computation was originally developed, the results were unstable. The technique of averaging the two most recent computations of the incremental distortion (Subsection 4.2.4) was developed to solve this problem. Since then, Landgrebe [23] and Widnall [24] have demonstrated both experimentally and theoretically that the wake beyond the first  $2\pi$  or so, probably is unstable. Thus, the geometry computed in this region represents an average value of the unstable oscillations.

#### 5.3 Airloads Results

The original intention was to compute airloads both with a rigid wake geometry and with a distorted wake geometry and then to compare the results. However, very large peaks appeared in the distorted wake airloads which either did not exist at all in the measured airloads or were much smaller. These peaks can easily be traced to the location of the tip vortex much closer to the rotor, over the forward portion of the rotor, in the distorted wake case (see Figs. 1 and 37a, for examples). This closer location of the tip vortex is explained physically

in Subsection 5.2.4. There remains the task of explaining the lack of these large peaks in the measured airloads.

The first thought was the lack of a tip vortex core. A solid body rotation vortex core model was introduced and various values of the vortex core radius  $\rho_c$  (normalized by rotor radius  $R$ ) were tried. It was found that  $\rho_c = 0.05$  (about one chord for the four-blade case) reduced the peaks to about the right size. This made the distorted wake airloads agree with the measured airloads about as well as the rigid wake airloads. Unfortunately, measurements of tip vortex characteristics show that  $\rho_c$  is more than an order of magnitude smaller than this (Subsection 2.4). The current best estimate of  $\rho_c$  for the four-blade case is 0.0025, which results in excessively large peaks in the distorted wake airloads. Thus, it became necessary to search for other close blade-vortex interaction effects to explain the lack of these peaks in the measured airloads.

The models developed for the various close blade-vortex interaction effects are described in Subsections 2.4, 2.5, and 3.2.4. These effects are evaluated here by comparing the results of a standard case, which includes all of these effects, with the results of removing the various effects one at a time. The effects of changing various parameters, such as the vortex-core size, are evaluated in a similar fashion. The four-blade,  $\mu = 0.18$  case (Table 2) is used for these evaluations. The standard set of inputs, about which perturbations are made is shown in Table 4.

#### 5.3.1 Lifting-Surface Solution

A close blade-vortex interaction induces a rapid spanwise variation of bound circulation on the blade. This, in turn, generates a trailing wake which induces airloads of the opposite sense on the blade (see Subsection 2.5.2). Originally, this extra trailing wake was represented by an approximate lifting-

line solution. However, Johnson [52,53] developed a lifting-surface solution for this case. An approximate, incompressible version of this solution is used here (Subsection 3.2.4).

The rigid wake (Fig. 39) and distorted wake (Fig. 40) airloads at 85% radius are shown. The results at other outboard radii are even more dramatic. In these results, the old lifting-line approximation is not used when the lifting-surface solution is removed. Instead, the effects of the extra trailing wake are simply neglected. This is because the lifting-line approximation is no longer available in the LDS-73 program. However, experience with older versions of LDS-73 indicates that the lifting-line approximation reduces the peaks by about half and the lifting-surface solution by half again. Thus, this extra trailing wake must be represented in airloads computations and the lifting-surface solution is by far the best way to do this.

#### 5.3.2 Tip Vortex-Core Radius

The effect of varying the burst vortex-core radius is shown in Fig. 41, at the 85% radius. The two values of  $\rho_g$  shown, bracket the standard value of  $0.10R$ . For distorted wake airloads at 85% radius, with  $\rho_g = 0.10R$ , see the solid line in Fig. 40. These results at 85% radius are typical of the outboard radial stations. Unfortunately, there is no sound theoretical or experimental basis for accurately estimating  $\rho_g$  at present. The results shown in Fig. 41 indicate that this problem should be carefully studied so that an accurate estimate of  $\rho_g$  can be obtained.

Distorted wake airloads were computed for the initial vortex core radius  $\rho_k$  equal to:  $.0050R$ ,  $.0015R$ ,  $.0010R$ , and  $.0005R$  as well as the standard value  $.0025R$ . The results for all except the smallest value were almost equal. The results for  $\rho_k = .0005R$  are compared to the standard case in Fig. 42, at 95% radius. This radius is typical and the differences

shown are not very significant. It should be realized, however, that this comparison would be dramatically different if tip vortex-core bursting were not used here. A hint of this is seen in the effect of variations in  $\rho_g$  (Fig. 41). To summarize, uncertainties in the initial vortex radius  $\rho_k$  are not important as long as tip vortex-core bursting is used, but a more accurate estimate of the burst vortex-core radius  $\rho_g$  would be useful.

### 5.3.3 Tip Vortex-Core Bursting

Tip vortex-core bursting is described in Subsections 2.5.1 and 3.2.4. The effect of burst vortex-core radius  $\rho_g$  was considered in Subsection 5.3.2. This subsection will consider the other parameters associated with bursting.

First, consider propagation of tip vortex-core bursting (Fig. 43). The important effect is at the 75% radius, as shown. At the outer radial stations there is not much effect. This is not very surprising because the close blade-tip-vortex interactions which occur near the blade tip are the trigger which initiates bursting and hence propagation. Thus, propagation does not have time to build up at these outboard stations. However, the effect is important at the 75% radius and nothing else has been found which can replace it.

To show the effect of tip vortex-core bursting alone, without propagation, this is compared with the no-bursting case in Fig. 44a (95% radius), Fig. 44b (85% radius), and in Fig. 44c (75% radius). The use of bursting without propagation is seen to make very little difference, except for an extra secondary peak at about  $\psi = 90^\circ$ . This peak is caused by bursting of the tip vortex from the  $\zeta = 180^\circ$  blade (i.e., the blade  $180^\circ$  away from the blade upon which airloads are computed). Since this secondary peak does not appear in the measured airloads, it is concluded that the very simple model of vortex bursting used here (i.e., an increase in tip vortex-core size from .0025R to

.10R) is inadequate. However, it is not possible to construct a better model without a better understanding of the whole process of tip vortex-core bursting, which would require a complete theoretical and experimental study of the subject. It is recommended that such a study be undertaken. Until then, the current model will be used.

One criterion for tip vortex-core bursting is that the tip vortex pass within  $(FVB)\rho_c$  of the blade, where FVB is an input constant and  $\rho_c$  is the tip vortex-core radius. The effect of changing FVB from the standard value of 20.0 to 1.0 is shown in Fig. 45, at 95% radius. The value of  $FVB = 1.0$  is probably much more realistic; however, 20.0 is made standard to correspond to the standard rigid wake case where the tip vortex is unrealistically far away from the rotor. In any case, the airloads results are clearly not very sensitive to FVB for the distorted wake case.

The other criterion for tip vortex-core bursting is how much of the tip vortex-line segment being considered has passed beneath the blade (see Subsection 3.2.4). The standard value of  $DVB = 0.0$  implies that all of the segment has passed beneath the blade,  $DVB = -0.5$  implies that only half of the segment has done so, and  $DVB = +0.5$  implies that the segment is one-half segment length behind the blade. The results at 85% radius for  $DVB = +0.5$  and  $DVB = -0.5$  are compared in Fig. 46. For the results with the standard value of  $DVB = 0.0$ , see the solid line in Fig. 40. The  $DVB = 0.0$  and the  $DVB = +0.5$  results are similar, while the  $DVB = -0.5$  results are quite different. It is hard to justify  $DVB = -0.5$  physically, indeed  $DVB = +0.5$  is probably the most realistic value. The current version of LDS-73 requires that any particular segment be 100% burst or 100% not burst. It would be desirable to make provision for partially bursting a segment and more research should be done on just when a segment bursts.

#### 5.3.4 Maximum Incremental Angle of Attack

There is a provision for a cutoff on the incremental angle of attack, due to any particular vortex-line segment (Subsection 3.2.7). This limit  $\Delta\alpha_{\max}$  is 0.05 radians for the standard case. It was thought that  $\Delta\alpha_{\max}$  might have an effect similar to tip vortex-core bursting and thus might be an alternative explanation for the small measured airloads peaks. Distorted wake airloads were computed for  $\Delta\alpha_{\max}$  of 0.03, 0.05, and 9.0 radians both with and without bursting. No effect was observed. Further investigation revealed that the maximum  $\Delta\alpha$  never reached 0.03 radians for these cases and that  $\Delta\alpha_{\max}$  would need to be less than 0.02 radians to have any effect. In the no-lifting surface solution case,  $\Delta\alpha$  does become as large as 0.075 radians; however,  $\Delta\alpha_{\max}$  is not intended to replace the lifting-surface solution. Thus,  $\Delta\alpha_{\max}$  is not important unless values smaller than 0.02 radians can be justified.

#### 5.3.5 Tip Vortex Roll-Up

The vortex sheet plus vortex-line tip vortex model is used to represent tip vortex roll-up (Subsection 2.5.3). The alternative is instantaneous roll-up (i.e., a vortex-line model for the tip vortex). The effect of instantaneous roll-up on a rigid wake airloads computation for the four-blade,  $\mu = 0.18$  case at 95% radius is shown in Fig. 47a. The effect of instantaneous roll-up on a distorted wake airloads computation for the same case, but with no bursting, is shown in Fig. 47b, at 85% radius. The effect on the rigid-wake case, with bursting included, is small; however, there is a substantial effect on the distorted wake case, without bursting. Thus, it is concluded that tip vortex roll-up can have a significant effect on the airloads in some cases. However, tip vortex roll-up cannot replace the propagation of tip vortex-core bursting since roll-up is included in the results shown in Fig. 43.

### 5.3.6 Tangentially-Induced Velocity

The component of the induced velocity which is tangential to the rotor blade chord is normally neglected compared to the sum of the rotational velocity ( $\eta\Omega R$ ) and the free-stream velocity ( $\mu\Omega R \sin\psi$ ). To test the validity of this assumption both rigid wake and distorted wake airloads were computed including the tangentially-induced velocity. In the rigid-wake case, the effect was negligible. In the distorted-wake case, the effect was small, except at the 85% radius (Fig. 48). The tangentially-induced velocities which produced the effect shown are only two or three percent of the total tangential velocity. Their effect is magnified by first harmonic flapping, however, because the tangentially-induced velocity consists primarily of a  $\sin\psi$  term, in this case. Thus tangentially-induced velocities can be significant in special cases.

### 5.3.7 Effect of Distortion on Airloads

A direct comparison of rigid vs. distorted wake airloads for the four-blade  $\mu = 0.18$  case is given in Fig. 2, at 95% radius. To compare the results at other radial stations match the solid line in Fig. 39 (rigid wake) with the solid line in Fig. 40 (distorted wake) for the 85% radius and match the solid line in Fig. 49 (rigid wake) with the solid line in Fig. 50 (distorted wake) for the 75% radius. The overall agreement with the measured data is about the same for this case.

If the effects of tip vortex-core bursting are eliminated and instantaneous roll-up is assumed, the distorted wake case (Fig. 50) becomes much worse than the rigid-wake case (Fig. 49), at the 75% radius. The key factor in this is the propagation of tip vortex-core bursting, as shown in Subsection 5.3.3. This effect is much less significant at the outer radial stations. If the lifting-surface solution is eliminated, the distorted-wake case (Fig. 40) again becomes much worse than the rigid-wake case (Fig. 39). This effect occurs at all radial stations (Subsection 5.3.1).

To check these results for another case, a six-blade,  $\mu = 0.108$  case was run. The rigid vs. distorted tip vortex-geometry comparison for this case is shown in Fig. 37a ( $\psi_s = 180^\circ$ ) and in Fig. 37b ( $\psi_s = 0^\circ$ ). The corresponding airloads comparison is shown in Fig. 51, at the 85% radius. These airloads were computed using the same standard inputs as the four-blade case (Table 4), with an adjustment of the initial vortex-core size due to the different aspect ratio of the rotor blades. The distorted wake result is substantially better than the rigid-wake result at the 85% radius shown. However, the comparison at other radial stations is less favorable, making the overall comparison only somewhat in favor of the distorted wake.

#### 5.4 Conclusions

The fundamental conclusion is that, over the forward portion of the rotor, the actual location of the tip vortex is much closer to the rotor than the rigid-wake assumption would predict. However, a lack of understanding of close blade-tip vortex interactions causes the computed airloads to be substantially larger than measured flight test data. This error tends to compensate for the rigid-wake assumption's error in the location of the tip vortex over the forward portion of the rotor, with the result that rigid-wake airloads computations agree fairly well with measured airloads. This same error causes airloads computed using the more accurate distorted tip vortex geometry to be too large.

A study was made of various possible close blade-tip vortex interaction effects. The largest one is the influence of the extra wake trailed during a close blade-vortex interaction on the airloads on that blade. This effect is well represented by Johnson's lifting-surface solution (Subsections 2.5.2 and 3.2.4). However, this effect is not sufficient to make the distorted wake airloads agree with the measured airloads. Thus, other effects were investigated.

The use of a sufficiently large tip vortex-core radius was found to reduce the distorted wake airloads by the necessary amount. However, the vortex-core radius required to achieve this result is about twenty times larger than that observed experimentally. This led to the concept of tip vortex-core bursting due to a close blade-tip vortex interaction. However, bursting alone does not explain the excessive distorted wake airloads at the more inboard radial stations such as the 75% radius. This led to the concept of propagation of bursting. Once a close blade-tip vortex interaction initiates bursting it is assumed to propagate along the tip vortex, ahead of the blade. This propagation of bursting is generally successful in reducing the distorted wake airloads to levels approximating those of the measured airloads.

Since tip vortex-core bursting is still controversial and propagation of bursting is speculative, a search was made for alternative explanations. Ham [54,55] has suggested that local separation limits the maximum incremental angle of attack due to any close blade-tip vortex interaction. The values of this limiting angle-of-attack increment required to have any effect on the case test are smaller than can be justified, however. The effects of tip vortex roll-up and of tangentially-induced velocities were also investigated. They both have modest effects on the airloads but they are not large enough or of the proper character to replace tip vortex-core bursting.

To summarize, the only satisfactory explanation found for the discrepancies between distorted wake airloads and measured airloads is a combination of a lifting-surface solution and tip vortex-core bursting with propagation. The lifting-surface solution is satisfactory; however, the bursting model is highly simplified because there is as yet no basis for a better model. The distorted wake airloads computed using these techniques are not much more accurate than rigid wake airloads. This is probably

due to an inadequate understanding of bursting and its propagation. However, it is possible that some other close blade-tip vortex interaction effect, not considered here, may also be important.

To make both airloads and wake geometry computations less expensive and hence more widely useful, a simplified wake model was developed which gives satisfactory results without great expense (Section 2). Special updating techniques were developed for computing the tip vortex distortion which reduce the expense by more than an order of magnitude (Subsection 4.2).

### 5.5 Recommendations

The principal recommendation is that a complete theoretical and experimental study of the close blade-tip vortex interaction problem be made, leading to a better understanding of the physics of the problem and to suitable mathematical models. Special emphasis should be given to the effect of close blade-tip vortex interactions on the tip vortex, including the possibility of tip vortex-core bursting. The possibility that bursting might propagate ahead of the blade which initiated it should be considered and the properties of a burst vortex need to be investigated so that a better model can be developed. The word bursting is used rather loosely here. It is generalized to include any change in the nature of the tip vortex, due to a close blade-vortex interaction, which changes the airloads induced by that tip vortex (see Subsection 2.5.1).

The formation and roll-up of the tip vortex should be studied as well. This is moderately important for airloads computations and it is thought to be the key to successful computation of the hovering tip vortex geometry. A study of the structure of the inboard trailing wake might yield useful results, but this is clearly less important than the previous recommendations.

Finally, various recommendations for improving the details of the wake model, the airloads computation, and the wake geometry computation are made in the main body of this report.

TABLE 1  
NORMALIZATION RULES

TYPE OF VARIABLE	NORMALIZATION
Length	$R$ = rotor radius (ft)
Time	$\Omega$ = rotor angular velocity (radians/sec)
Speed	$\Omega R = V_T$ = tip speed (ft/sec)
Angle	Radian measure
Circulation	$2\pi b \Omega R$ (ft <sup>2</sup> /sec), where $b$ = rotor blade semichord
Airload	$\rho c (\Omega R)^2 / 2$ (lb/in), where $c$ = rotor blade chord
	Note: Since the unit of length normally used here is feet, just using the normal values of $\rho, \Omega c$ , and $\Omega R$ will give (lb/ft) This must be divided by 12 to get (lb/in)

\* Times are CPU time in seconds on an IBM 370/168 running under release 21.7 of OS/MVT with release 21.6 FORTRAN G1. Most of the CALCOMP plot time is excluded from the WG times given. The WG times are for two iterations and the LDS times are for 5 iterations. However, the induced velocity influence coefficient matrix (QMAT) is only computed in the LDS computations.

TABLE 4  
STANDARD AIRLOADS INPUTS

Vortex Core Radius (normalized by R)

- a) Initial value  $\rho_k = 0.0025$
- b) Burst value  $\rho_g = 0.100$
- c) Vortex sheet value  $\rho_{VS} = 0.0025$

Vortex Core Bursting Parameters

- a) Distance from blade DVB = 0.0 segment lengths
- b) Distance below blade FVB = 20.0 vortex core radii

Bursting Propagation Parameters

- a) Propagation rate NPRP = 3 (increment bursting azimuth angle by one  $\Delta\phi$  for every NPRP  $\Delta\phi$  steps in age)
- b) Propagation range NRNG = 16, end propagation at  $\phi = (NRNG-1)\Delta\phi$

Lifting-Surface Solution - included

Maximum incremental angle of attack  $\alpha_m = 0.05$  radians

Vortex Sheet Plus Vortex-Line Tip-Vortex Model

Roll-up rate  $f_t^D = 0.05$  (fraction of total tip vortex circulation which is in the vortex sheet decreases by  $f_t^D$  each  $\Delta\phi$  step)

# APPENDIX A

## VELOCITY INDUCED BY A STRAIGHT VORTEX LINE SEGMENT

Consider a straight vortex line segment. Label the ends of the vortex line segment points  $P_a$  and  $P_b$ . The nondimensional circulation is allowed to vary linearly from  $\gamma_a$  at point  $P_a$  to  $\gamma_b$  at point  $P_b$ . The induced velocity is computed at point  $P_\eta$ . Point  $P_\eta$  is located by vectors  $\vec{a}$  and  $\vec{b}$  from point  $P_\eta$  to points  $P_a$  and  $P_b$  (Fig. A.1). The TPP referenced x, y, z coordinate system is used with the origin at point  $P_\eta$ .

The induced velocity is computed by using the Biot Savart Relation [34]:

$$dq_{f_1} = \frac{\Gamma \sin \theta ds_1}{4\pi r_1^2} \quad (A.1)$$

where  $dq_{f_1}$  is the induced velocity at point  $P_\eta$  and is perpendicular to the  $r_1$ ,  $ds_1$  plane,  $ds_1$  is an element of the vortex line,  $\Gamma$  is the circulation of  $ds_1$ ,  $r_1$  is the distance from point  $P_\eta$  to  $ds_1$ , and  $\theta$  is the angle between  $r_1$  and  $ds_1$  (Fig. A.1). Now define the following nondimensional versions of the variables:

$$dq_{f_{VL}} \equiv dq_{f_1} / 2R \quad (A.2)$$

$$r \equiv r_1 / R \quad (A.3)$$

$$ds \equiv ds_1 / R \quad (A.4)$$

$$\gamma \equiv \Gamma / 2\pi b 2R \quad (A.5)$$

Further, define  $h$  as the perpendicular distance (nondimensional by  $R$ ) from point  $P_\eta$  to the vortex line segment and  $\phi$  as the angle between  $h$  and  $r$  (Fig. A.1). Now substituting in Eq. A.1:

$$dq_{f_{VL}} = \gamma \left( \frac{b}{2R} \right) \frac{\sin \theta ds}{r^2} \quad (A.6)$$

From Fig. A.1:

$$\sin \theta = \cos \phi = \frac{h}{r} \quad (\text{A.7})$$

$$ds = d(h \tan \phi) = \left( \frac{h}{\cos^2 \phi} \right) d\phi \quad (\text{A.8})$$

Now Eq. A.6 can be rewritten in terms of  $h$  and  $\phi$ :

$$dq_{VL} = \gamma \left( \frac{b}{2R} \right) \left( \frac{\cos \phi}{h} \right) d\phi \quad (\text{A.9})$$

Since  $\gamma$  is a linear variation from  $\gamma_a$  at point  $P_a$  to  $\gamma_b$  at point  $P_b$ , it can be written as (see Fig. A.1):

$$\gamma = \gamma_a + (\gamma_b - \gamma_a) \left( \frac{h \cot \alpha + h \tan \phi}{h \cot \alpha + h \cot \beta} \right) \quad (\text{A.10})$$

Substituting into Eq. A.9 and integrating from  $\phi = \alpha - \pi/2$  to  $\phi = \pi/2 - \beta$ :

$$q_{VL} = \gamma_a \left( \frac{b}{2R} \right) \int_{\alpha - \frac{\pi}{2}}^{\frac{\pi}{2} - \beta} \left\{ \frac{\cos \phi}{h} + \left( \frac{\gamma_b - \gamma_a}{\gamma_a} \right) \left[ \frac{\cot \alpha \cos \phi + \sin \phi}{h (\cot \alpha + \cot \beta)} \right] \right\} d\phi \quad (\text{A.11})$$

$$q_{VL} = \gamma_a \left( \frac{b}{2R} \right) \left\{ \left( \frac{\cos \alpha + \cos \beta}{h} \right) + \left( \frac{\gamma_b - \gamma_a}{\gamma_a} \right) \left[ \frac{\sin \alpha - \sin \beta + \cot \alpha (\cos \alpha + \cos \beta)}{h (\cot \alpha + \cot \beta)} \right] \right\} \quad (\text{A.12})$$

For the special case of constant circulation ( $\gamma_a = \gamma_b$ ) this reduces to:

$$q_{VL} = \gamma_a \left( \frac{b}{2R} \right) \left( \frac{\cos \alpha + \cos \beta}{h} \right) \quad (\text{A.13})$$

To find  $q_{VL}$  in terms of  $\vec{a}$  and  $\vec{b}$ , define  $\vec{c}$  (Fig. A.1).

$$\vec{c} \equiv \vec{b} - \vec{a} \quad (\text{A.14})$$

Now using the dot and cross product relations and Fig. A.1:

$$-\vec{a} \cdot \vec{c} = (-\vec{a}) \cdot \vec{c} = |\vec{a}| |\vec{c}| \cos \alpha \quad (\text{A.15})$$

$$\vec{b} \cdot \vec{c} = (-\vec{c}) \cdot (-\vec{b}) = |\vec{b}| |\vec{c}| \cos \beta \quad (\text{A.16})$$

$$|\vec{a} \times \vec{c}| = |\vec{a}| |\vec{c}| \sin \alpha \quad (\text{A.17})$$

$$|\vec{b} \times \vec{c}| = |\vec{b}| |\vec{c}| \sin \beta \quad (\text{A.18})$$

$$h = |\vec{a}| \sin \alpha = \frac{|\vec{a} \times \vec{c}|}{|\vec{c}|} \quad (\text{A.19})$$

Using the definition of  $\vec{c}$  and recalling that a vector crossed with itself is zero:

$$|\vec{a} \times \vec{c}| = |\vec{a} \times (\vec{b} - \vec{a})| = |\vec{a} \times \vec{b}| \quad (\text{A.20})$$

$$|\vec{b} \times \vec{c}| = |\vec{b} \times (\vec{b} - \vec{a})| = |\vec{a} \times \vec{b}| \quad (\text{A.21})$$

Recall that the induced velocity is perpendicular to the  $r_1 ds_1$  plane, which is the same as the  $\vec{a}, \vec{b}$  plane. Define positive circulation such that  $\vec{q}_{VL}$  points into the paper in Fig. A.1. Now  $\vec{q}_{VL}$  can be written as:

$$\vec{q}_{VL} = q_{VL} \frac{\vec{a} \times \vec{b}}{|\vec{a} \times \vec{b}|} \quad (\text{A.22})$$

Substituting into Eq. A.12:

$$\begin{aligned} \vec{q}_{VL} = \gamma_a \left( \frac{b}{2R} \right) & \left\{ \left[ \frac{(|\vec{a}| + |\vec{b}|)(|\vec{a}||\vec{b}| - \vec{a} \cdot \vec{b})}{|\vec{a}||\vec{b}||\vec{a} \times \vec{b}|^2} \right] \left[ 1 + \left( \frac{\gamma_b - \gamma_a}{\gamma_a} \right) \left( \frac{|\vec{a}|^2 - \vec{a} \cdot \vec{b}}{|\vec{a}|^2 + |\vec{b}|^2 - 2\vec{a} \cdot \vec{b}} \right) \right] \right. \\ & \left. + \left( \frac{\gamma_b - \gamma_a}{\gamma_a} \right) \left[ \frac{|\vec{b}| - |\vec{a}|}{|\vec{a}||\vec{b}|(|\vec{a}|^2 + |\vec{b}|^2 - 2\vec{a} \cdot \vec{b})} \right] \right\} (\vec{a} \times \vec{b}) \end{aligned} \quad (\text{A.23})$$

For the special case of constant circulation ( $\gamma_a = \gamma_b$ ), this reduces to:

$$\vec{q}_{VL} = \gamma_a \left( \frac{b}{2R} \right) \left[ \frac{(|\vec{a}| + |\vec{b}|)(|\vec{a}||\vec{b}| - \vec{a} \cdot \vec{b})}{|\vec{a}||\vec{b}||\vec{a} \times \vec{b}|^2} \right] (\vec{a} \times \vec{b}) \quad (\text{A.24})$$

## APPENDIX B

### VELOCITY INDUCED BY A PLANE RECTANGULAR VORTEX SHEET

#### B.1 Computation of the Induced Velocity in Vortex-Sheet

##### Based Coordinates

Consider a plane, rectangular vortex sheet whose circulation is aligned parallel to one pair of edges, hereafter called the front and back edges. The circulation is allowed to vary linearly from  $\gamma_a$  to  $\gamma_b$  parallel to the circulation vector but remains constant perpendicular to the circulation vector. The induced velocity is computed at point  $P_\eta$ . Point  $P_\eta$  is located by vectors  $\vec{a}$  and  $\vec{b}$  from point  $P_\eta$  to the ends of the forward edge of the vortex sheet, points  $P_a$  and  $P_b$ , and by the perpendicular distance  $z_1$  from point  $P_\eta$  to the vortex sheet (Fig. B.1).

A right-handed, rectangular coordinate system  $(\tilde{x}, \tilde{y}, \tilde{z})$  with its origin at point  $P_\eta$  is chosen. The  $\tilde{z}$  axis is perpendicular to the vortex sheet while  $\tilde{x}$  and  $\tilde{y}$  are parallel to it. The  $\tilde{y}$  axis is parallel to the front and back edges, while the  $\tilde{x}$  axis points forward perpendicular to the front edge (Fig. B.1). The length of the vortex sheet in the  $\tilde{x}$  direction is  $\Delta\tilde{x}$  with the front edge at  $\tilde{x} = x_1$  and the back edge at  $\tilde{x} = x_2$ . The width of the vortex sheet in the  $\tilde{y}$  direction is  $|\vec{c}| = |\vec{b} - \vec{a}|$  (Fig. B.1).

To compute the induced velocity contribution of the vortex sheet at point  $P_\eta$  ( $\vec{a}_{VS}$ ), the sheet is visualized as an infinite number of parallel vortex lines each of infinitesimal circulation. The geometry of the vortex line at  $\tilde{x} = x_1$  relative to point  $P_\eta$  is specified by  $\vec{a}$  and  $\vec{b}$ . To compute the induced velocity contribution of this vortex line, it is helpful to define the parameters  $c_a$ ,  $c_b$ ,  $h_1$ ,  $\vec{n}_1$ ,  $\alpha_1$ , and  $\beta_1$  with the aid of Fig. B.1. The perpendicular distance from point  $P_\eta$  to the vortex line ( $\vec{c}$ ) or its extension is  $h_1$ . The distances from the intersection of  $h_1$  with  $\vec{c}$  or its extension to points  $P_a$  and  $P_b$  are  $c_a$  and  $c_b$ , respectively. The angles between  $\vec{a}$  and  $\vec{c}$  and between  $\vec{b}$  and  $\vec{c}$  are  $\alpha_1$  and  $\beta_1$ , respectively.

The circulation of the vortex sheet segment (nonD by 2n(b)R) varies

linearly from  $\gamma_a$  at the  $P_a$  edge of the sheet to  $\gamma_b$  at the  $P_b$  edge. Spreading this over  $\Delta\tilde{x}$ , the circulation of each infinitesimal vortex line varies from  $[(\gamma_a/\Delta\tilde{x}) d\tilde{x}]$  at the  $P_a$  end to  $[(\gamma_b/\Delta\tilde{x}) d\tilde{x}]$  at the  $P_b$  end. Using the expression for the induced velocity of a straight vortex line segment from Eq. A.14, the induced velocity contribution of the vortex line at  $\tilde{x} = x_1$  (nondimensional by tip speed) is:

$$dq_1 = \left(\frac{b}{2R}\right) \left(\frac{\gamma_a}{\Delta\tilde{x}}\right) d\tilde{x} \hat{n} \left\{ \left( \frac{\cos\alpha_1 + \cos\beta_1}{h_1} \right) + \left( \frac{\gamma_b - \gamma_a}{\gamma_a} \right) \left[ \frac{\sin\alpha_1 - \sin\beta_1 + \cot\alpha_1 (\cos\alpha_1 + \cos\beta_1)}{h_1 (\cot\alpha_1 + \cot\beta_1)} \right] \right\} \quad (B.1)$$

For the special case of a constant circulation strength vortex line ( $\gamma_a = \gamma_b$ ) only the first term remains.

Now consider the induced velocity contribution of a general vortex line at  $\tilde{x}$ . Since the vortex sheet is rectangular,  $c_a$  and  $c_b$  remain constant for all  $\tilde{x}$ . The general values of  $h$ ,  $\hat{n}$ ,  $\alpha$ , and  $\beta$  are, however, functions of  $\tilde{x}$  and are denoted by dropping the subscript 1 from the values at  $\tilde{x} = x_1$ . The induced velocity contribution of the vortex sheet is obtained by integration of the vortex line contributions in the positive  $\tilde{x}$  direction from  $\tilde{x} = x_2$  to  $\tilde{x} = x_1$ . This gives:

$$\vec{P}_{vs} = \left(\frac{b}{2R}\right) \left(\frac{\gamma_a}{\Delta\tilde{x}}\right) \left\{ \int_{x_2}^{x_1} \left( \frac{\cos\alpha + \cos\beta}{h} \right) \hat{n} d\tilde{x} + \left( \frac{\gamma_b - \gamma_a}{\gamma_a} \right) \int_{x_2}^{x_1} \left[ \frac{\sin\alpha - \sin\beta + \cot\alpha (\cos\alpha + \cos\beta)}{h (\cot\alpha + \cot\beta)} \right] \hat{n} d\tilde{x} \right\} \quad (B.2)$$

To integrate Eq. 8.2,  $h$ ,  $\hat{n}$ ,  $\alpha$ , and  $\beta$  must be expressed in terms of  $\tilde{x}$ . From Fig. B.1:

$$h = \sqrt{\tilde{x}^2 + z_{\perp}^2} \quad (B.3)$$

$$\sin \alpha = \frac{h}{\sqrt{h^2 + c_a^2}} = \frac{\sqrt{\tilde{x}^2 + z_{\perp}^2}}{\sqrt{\tilde{x}^2 + z_{\perp}^2 + c_a^2}} \quad (B.4)$$

$$\sin \beta = \frac{h}{\sqrt{h^2 + c_b^2}} = \frac{\sqrt{\tilde{x}^2 + z_{\perp}^2}}{\sqrt{\tilde{x}^2 + z_{\perp}^2 + c_b^2}} \quad (B.5)$$

$$\cos \alpha = \frac{c_a}{\sqrt{\tilde{x}^2 + z_{\perp}^2 + c_a^2}} \quad (B.6)$$

$$\cos \beta = \frac{c_b}{\sqrt{\tilde{x}^2 + z_{\perp}^2 + c_b^2}} \quad (B.7)$$

Observing that  $\hat{n}$  is perpendicular to  $h$  and in the plane formed by  $h$  and  $z_{\perp}$ :

$$\hat{n} = \frac{-z_{\perp}}{\sqrt{\tilde{x}^2 + z_{\perp}^2}} \hat{l}_{\tilde{x}} + \frac{\tilde{x}}{\sqrt{\tilde{x}^2 + z_{\perp}^2}} \hat{l}_{\tilde{z}} \quad (B.8)$$

where  $\hat{l}_{\tilde{x}}$  and  $\hat{l}_{\tilde{z}}$  are unit vectors in the  $\tilde{x}$  and  $\tilde{z}$  directions, respectively.

Equation B.2 can now be rewritten in terms of  $\tilde{x}$  as:

$$\begin{aligned} \vec{f}_{vs} = & \left( \frac{b}{2R} \right) \left( \frac{Y_a}{\Delta \tilde{x}} \right) \left\{ \int_{x_2}^{x_1} \left( \frac{c_a}{\sqrt{c_a^2 + \tilde{x}^2 + z_{\perp}^2}} + \frac{c_b}{\sqrt{c_b^2 + \tilde{x}^2 + z_{\perp}^2}} \right) \left( \frac{-z_{\perp} \hat{l}_{\tilde{x}} + \tilde{x} \hat{l}_{\tilde{z}}}{\tilde{x}^2 + z_{\perp}^2} \right) d\tilde{x} \right. \\ & + \left( \frac{Y_b - Y_a}{Y_a} \right) \int_{x_2}^{x_1} \left[ \frac{1}{\sqrt{c_a^2 + \tilde{x}^2 + z_{\perp}^2}} - \frac{1}{\sqrt{c_b^2 + \tilde{x}^2 + z_{\perp}^2}} \right. \\ & \left. \left. + \left( \frac{c_a}{\tilde{x}^2 + z_{\perp}^2} \right) \left( \frac{c_a}{\sqrt{c_a^2 + \tilde{x}^2 + z_{\perp}^2}} + \frac{c_b}{\sqrt{c_b^2 + \tilde{x}^2 + z_{\perp}^2}} \right) \left( \frac{-z_{\perp} \hat{l}_{\tilde{x}} + \tilde{x} \hat{l}_{\tilde{z}}}{c_a + c_b} \right) d\tilde{x} \right] \right\} \end{aligned}$$

(B.9)

Equation B.9 has four fundamentally different integrals in it:

$$I_1 = \int_{x_2}^{x_1} \left[ \left( \frac{c_a}{\sqrt{c_a^2 + \tilde{x}^2 + z_1^2}} + \frac{c_b}{\sqrt{c_b^2 + \tilde{x}^2 + z_1^2}} \right) \left( \frac{-z_1 d\tilde{x}}{\tilde{x}^2 + z_1^2} \right) \right] \quad (B.10)$$

$$I_2 = \int_{x_2}^{x_1} \left[ \left( \frac{c_a}{\sqrt{c_a^2 + \tilde{x}^2 + z_1^2}} + \frac{c_b}{\sqrt{c_b^2 + \tilde{x}^2 + z_1^2}} \right) \left( \frac{\tilde{x} d\tilde{x}}{\tilde{x}^2 + z_1^2} \right) \right] \quad (B.11)$$

$$I_3 = \int_{x_2}^{x_1} \left[ \left( \frac{1}{\sqrt{c_a^2 + \tilde{x}^2 + z_1^2}} - \frac{1}{\sqrt{c_b^2 + \tilde{x}^2 + z_1^2}} \right) (-z_1 d\tilde{x}) \right] \quad (B.12)$$

$$I_4 = \int_{x_2}^{x_1} \left[ \left( \frac{1}{\sqrt{c_a^2 + \tilde{x}^2 + z_1^2}} - \frac{1}{\sqrt{c_b^2 + \tilde{x}^2 + z_1^2}} \right) (\tilde{x} d\tilde{x}) \right] \quad (B.13)$$

The integrals can be looked up in a table or integrated directly. To simplify writing the results define:

$$S_{1a} = \sqrt{c_a^2 + x_1^2 + z_1^2} \quad (B.14)$$

$$S_{1b} = \sqrt{c_b^2 + x_1^2 + z_1^2} \quad (B.15)$$

$$S_{2a} = \sqrt{c_a^2 + x_2^2 + z_1^2} \quad (B.16)$$

$$S_{2b} = \sqrt{c_b^2 + x_2^2 + z_1^2} \quad (B.17)$$

The integrals are evaluated at  $x_1$  and  $x_2$  and algebraic manipulation is used to minimize the number of natural log functions which saves computer time.

$$I_1 = \tan^{-1} \left( \frac{C_a X_2}{Z_{\perp} S_{2a}} \right) - \tan^{-1} \left( \frac{C_a X_1}{Z_{\perp} S_{1a}} \right) + \tan^{-1} \left( \frac{C_b X_2}{Z_{\perp} S_{2b}} \right) - \tan^{-1} \left( \frac{C_b X_1}{Z_{\perp} S_{1b}} \right) \quad (B.18)$$

$$\begin{aligned} I_2 &= \frac{1}{2} \left[ \ln \left( \frac{S_{1a} - C_a}{S_{1a} + C_a} \right) - \ln \left( \frac{S_{2a} - C_a}{S_{2a} + C_a} \right) + \ln \left( \frac{S_{1b} - C_b}{S_{1b} + C_b} \right) - \ln \left( \frac{S_{2b} - C_b}{S_{2b} + C_b} \right) \right] \\ &= \frac{1}{2} \ln \left[ \frac{(S_{1a} - C_a)(S_{2a} + C_a)(S_{1b} - C_b)(S_{2b} + C_b)}{(S_{1a} + C_a)(S_{2a} - C_a)(S_{1b} + C_b)(S_{2b} - C_b)} \right] \end{aligned} \quad (B.19)$$

$$\begin{aligned} I_3 &= \ln(S_{2a} + X_2) - \ln(S_{1a} + X_1) - \ln(S_{2b} + X_2) + \ln(S_{1b} + X_1) \\ &= \ln \left[ \frac{(S_{2a} + X_2)(S_{1b} + X_1)}{(S_{1a} + X_1)(S_{2b} + X_2)} \right] \end{aligned} \quad (B.20)$$

$$I_4 = S_{1a} - S_{2a} - S_{1b} + S_{2b} \quad (B.21)$$

Finally, the induced velocity contribution of the vortex sheet at point  $P_{\eta}$  (nondimensional by tip speed) can be written as:

$$\begin{aligned} \vec{q}_{vs} &= \left( \frac{b}{2R} \right) \left( \frac{Y_a}{\Delta \tilde{x}} \right) \left\{ I_1 \vec{\hat{t}}_{\tilde{x}} + I_2 \vec{\hat{t}}_{\tilde{z}} + \left( \frac{Y_b - Y_a}{Y_a} \right) \right. \\ &\quad \left. \left[ \left( \frac{C_a}{C_a + C_b} \right) (I_1 \vec{\hat{t}}_{\tilde{x}} + I_2 \vec{\hat{t}}_{\tilde{z}}) + \left( \frac{1}{C_a + C_b} \right) (I_3 \vec{\hat{t}}_{\tilde{x}} + I_4 \vec{\hat{t}}_{\tilde{z}}) \right] \right\} \end{aligned} \quad (B.22)$$

For the special case of a constant circulation vortex sheet ( $\gamma_a = \gamma_b$ ) this simplifies to:

$$\vec{q}_{\text{vs}} = \left(\frac{b}{2R}\right) \left(\frac{\gamma_a}{\Delta \vec{x}}\right) \left(I_1 \vec{e}_x + I_2 \vec{e}_z\right) \quad (\text{B.23})$$

Notice that  $I_1$  (the  $\tan^{-1}$  integral) has no singularities, but  $I_2$  (the  $\ln$  integral) is singular near the edges of the vortex sheet.  $I_1$  can be said to represent the fundamental nature of the vortex sheet and  $I_2$  to represent the edges. To explore the edge singularity, consider the cases:  $x_1 = \epsilon$ ,  $\Delta \vec{x} = \Delta x$ ,  $c_a = c_b = c$ ,  $z_1 = 0$ , and  $\epsilon \ll \Delta x, c$ . From Eq. B.19:

$$I_2 = \frac{1}{2} \ln \left[ \frac{(S_1 - c)^2 (S_2 + c)^2}{(S_1 + c)^2 (S_2 - c)^2} \right] = \ln \left[ \frac{(S_1 - c)(S_2 + c)}{(S_1 + c)(S_2 - c)} \right] \quad (\text{B.24})$$

Expanding  $S_1$  and  $S_2$  in  $\epsilon$ :

$$S_1 = \sqrt{c^2 + \epsilon^2} = c + \frac{\epsilon^2}{2c} + \text{HOT} \quad (\text{B.25})$$

$$\begin{aligned} S_2 &= \sqrt{c^2 + \Delta x^2 - 2\epsilon\Delta x + \epsilon^2} \\ &= \sqrt{c^2 + \Delta x^2} + \frac{\epsilon(\epsilon - 2\Delta x)}{2\sqrt{c^2 + \Delta x^2}} + \text{HOT} \end{aligned} \quad (\text{B.26})$$

Dropping higher-order terms (HOT) and plugging in to Eq. B.24:

$$I_2 \approx \ln \left[ \frac{\left( \sqrt{c^2 + \Delta x^2} + \frac{\epsilon(\epsilon - 2\Delta x)}{2\sqrt{c^2 + \Delta x^2}} + c \right) \left( c + \frac{\epsilon^2}{2c} - c \right)}{\left( \sqrt{c^2 + \Delta x^2} + \frac{\epsilon(\epsilon - 2\Delta x)}{2\sqrt{c^2 + \Delta x^2}} - c \right) \left( c + \frac{\epsilon^2}{2c} + c \right)} \right] \quad (\text{B.27})$$

Now, for  $\epsilon$  very, very small:

$$I_2 \approx \ln \left[ \left( \frac{\sqrt{c^2 + \Delta x^2} + c}{\sqrt{c^2 + \Delta x^2} - c} \right) \left( \frac{\epsilon}{2c} \right)^2 \right] \approx 2 \ln \left( \frac{\epsilon}{2c} \right) \quad (\text{B.28})$$

A similar exercise with  $\epsilon \ll \Delta x \ll c$  results in  $I_2 \sim \ln(\epsilon/\Delta x)$ . Thus there is a logarithmic singularity when  $x_1$  or  $x_2$  becomes small compared with the

dimensions of the vortex sheet. The way to avoid this is to stay away from the edges of the sheet, since in reality there are no such step changes in circulation.

## B.2 Transformation from Vortex Sheet Based Coordinates to TPP Coordinates

To be able to add the induced velocity contributions of the many vortex sheets of the wake model, a common coordinate system must be used. Since vortex sheet orientation varies greatly, the  $\tilde{x}, \tilde{y}, \tilde{z}$  system is not satisfactory. Since  $\vec{a}$  and  $\vec{b}$  are already available in the  $x, y, z$  (TPP referenced) coordinate system and all vortex line segment computations are done in this coordinate system it is chosen. To review, it is a right-handed, rectangular coordinate system where the  $z$  axis points downward perpendicular to the TPP, the  $y$  axis points downstream and parallel to the TPP, and the  $x$  axis points to starboard parallel to the TPP.

It is also necessary to express the vortex sheet parameters  $c_a, c_b, z_1, x_1, x_2$ , and  $\Delta\tilde{x}$  in terms of parameters similar to those used in vortex line computations. The vectors  $\vec{a}$  and  $\vec{b}$  from point  $P_\eta$  to points  $P_a$  and  $P_b$  on the forward edge of the vortex sheet are analogous to the  $\vec{a}$  and  $\vec{b}$  from point  $P_\eta$  to points  $P_a$  and  $P_b$  at the ends of a vortex line segment. In addition, the length of the vortex sheet  $\Delta\tilde{x}$  and  $z_m$ , the  $z$  component of a vector from point  $P_\eta$  to the midpoint of the  $\tilde{x} = x_2$  edge of the vortex sheet are used to completely specify the vortex sheet geometry.

Let  $\vec{i}, \vec{j}, \vec{k}$  be unit vectors along the  $x, y, z$  axes, respectively. Now  $\vec{a}$  and  $\vec{b}$  can be written in the  $x, y, z$  coordinate system as:

$$\vec{a} = x_a \vec{i} + y_a \vec{j} + z_a \vec{k} \quad (\text{B.29})$$

$$\vec{b} = x_b \vec{i} + y_b \vec{j} + z_b \vec{k} \quad (\text{B.30})$$

Recall the definition of  $\vec{c}$  (Fig. B.2):

$$\vec{c} = \vec{b} - \vec{a} \quad (\text{B.31})$$

Define:

$$\Delta x = x_b - x_a \quad (\text{B.32})$$

$$\Delta y \equiv y_b - y_a \quad (\text{B.33})$$

$$\Delta z \equiv z_b - z_a \quad (\text{B.34})$$

Therefore:  $\vec{c} = \Delta x \vec{i} + \Delta y \vec{j} + \Delta z \vec{k} \quad (\text{B.35})$

$$|\vec{c}|^2 = \Delta x^2 + \Delta y^2 + \Delta z^2 \quad (\text{B.36})$$

From Fig. B.2:  $c_a = |\vec{a}| \sin \alpha \quad (\text{B.37})$

Now using the dot product relation:

$$\vec{c} \cdot (-\vec{a}) = -\vec{c} \cdot \vec{a} = |\vec{c}| |\vec{a}| \sin \alpha \quad (\text{B.38})$$

Therefore:

$$c_a = \frac{-\vec{c} \cdot \vec{a}}{|\vec{c}|} = \frac{-(x_a \Delta x + y_a \Delta y + z_a \Delta z)}{\sqrt{\Delta x^2 + \Delta y^2 + \Delta z^2}} \quad (\text{B.39})$$

From Fig. B.2:  $\vec{c}_a = |\vec{c}| - c_a \quad (\text{B.40})$

To find the relationship between the  $\tilde{x}$ ,  $\tilde{y}$ ,  $\tilde{z}$  and the  $x$ ,  $y$ ,  $z$  coordinate systems, define the  $x$ ,  $y$ ,  $z$  components of the  $\hat{i}_{\tilde{x}}$ ,  $\hat{i}_{\tilde{y}}$ , and  $\hat{i}_{\tilde{z}}$  unit vectors:

$$\vec{c}_x = x_x \vec{i} + y_x \vec{j} + z_x \vec{k} \quad (\text{B.41})$$

$$\vec{c}_y = x_y \vec{i} + y_y \vec{j} + z_y \vec{k} \quad (\text{B.42})$$

$$\vec{c}_z = x_z \vec{i} + y_z \vec{j} + z_z \vec{k} \quad (\text{B.43})$$

Now since  $\vec{c}$  is parallel to the  $\tilde{y}$  axis (Fig. B.2):

$$\vec{c}_y = \frac{\vec{c}}{|\vec{c}|} \quad (\text{B.44})$$

$$x_y = \frac{\Delta x}{|\vec{c}|} \quad (\text{B.45})$$

$$y_y = \frac{\Delta y}{|\vec{c}|} \quad (\text{B.46})$$

$$z_y = \frac{\Delta z}{|\vec{z}|} \quad (\text{B.47})$$

Consider a vector  $\vec{s}$  running from the midpoint of the  $\tilde{x} = x_2$  edge of the vortex sheet to the midpoint of the  $\tilde{x} = x_1$  edge. The length of  $\vec{s}$  is the length of the vortex sheet ( $\Delta\tilde{x}$ ), (Fig. B.3). Since  $\vec{s}$  is parallel to the  $\tilde{x}$  axis, it is parallel to the unit vector  $\hat{i}_{\tilde{x}}$ . The  $z$  coordinate of the  $\tilde{x} = x_2$  end of  $\vec{s}$  is  $z_m$  from the definition of  $z_m$ . The  $z$  coordinate of the  $\tilde{x} = x_1$  end of  $\vec{s}$  is the average of the  $z$  coordinates of the two ends of that edge of the vortex sheet ( $x_a$  and  $x_b$ ). Now the  $z$  component of  $\hat{i}_{\tilde{x}}$  is the difference between the  $z$  coordinates of the two ends of  $\vec{s}$  divided by the length of  $\vec{s}$ . Therefore:

$$z_x = \left[ \left( \frac{z_a + z_b}{2} \right) - z_m \right] / \Delta\tilde{x} \quad (\text{B.48})$$

To find the other two components of  $\hat{i}_{\tilde{x}}$ , recall that  $\hat{i}_{\tilde{x}}$  is a unit vector. Therefore,

$$|\vec{z}_{\tilde{x}}| = x_x^2 + y_x^2 + z_x^2 = 1.0 \quad (\text{B.49})$$

and that  $\hat{i}_{\tilde{x}}$  is perpendicular to  $\hat{i}_{\tilde{y}}$ . Therefore:

$$\vec{z}_{\tilde{x}} \cdot \vec{z}_{\tilde{y}} = \frac{x_x \Delta x + y_x \Delta y + z_x \Delta z}{|\vec{z}|} = 0.0 \quad (\text{B.50})$$

This gives two equations, B.49 and B.50 which can be solved for  $x_x$  and  $y_x$  with the result that:

$$x_x = \frac{-z_x \Delta x \Delta z + \Delta y \sqrt{(\Delta x^2 + \Delta y^2) - z_x^2 |\vec{z}|^2}}{\Delta x^2 + \Delta y^2} \quad (\text{B.51})$$

$$y_x = \frac{-z_x \Delta y \Delta z - \Delta x \sqrt{(\Delta x^2 + \Delta y^2) - z_x^2 |\vec{z}|^2}}{\Delta x^2 + \Delta y^2} \quad (\text{B.52})$$

To find  $\hat{i}_{\tilde{z}}$ , recall that for a right-handed coordinate system:

$$\vec{z} = \vec{z}_x \times \vec{z}_y \quad (\text{B.53})$$

This relation implies the following components for  $\vec{i}_z$ :

$$x_z = \frac{y_x \Delta z - z_x \Delta y}{|\vec{z}|} \quad (\text{B.54})$$

$$y_z = \frac{z_x \Delta x - x_x \Delta z}{|\vec{z}|} \quad (\text{B.55})$$

$$z_z = \frac{x_x \Delta y - y_x \Delta z}{|\vec{z}|} \quad (\text{B.56})$$

The parameters  $x_1$ ,  $x_2$ , and  $z_1$  remain to be derived in terms of  $x$ ,  $y$ ,  $z$  coordinates. To do this, consider a vector  $\vec{h}$  which is the perpendicular dropped from point  $P_\eta$  to the  $\vec{x} = x_1$  edge of the vortex sheet (Fig. B.3). Note that the length of  $\vec{h}$  is  $h_1$ , as was used in Section B.1 of this appendix.

Define the  $x$ ,  $y$ ,  $z$  components of  $\vec{h}$  as:

$$\vec{h} = x_h \vec{i} + y_h \vec{j} + z_h \vec{k} \quad (\text{B.57})$$

Now from Fig. B.2:

$$\vec{h} = \vec{a} + \vec{c} \left( \frac{c_a}{|\vec{z}|} \right) \quad (\text{B.58})$$

This relation implies that:

$$x_h = x_a + \Delta x \left( \frac{c_a}{|\vec{z}|} \right) \quad (\text{B.59})$$

$$y_h = y_a + \Delta y \left( \frac{c_a}{|\vec{z}|} \right) \quad (\text{B.60})$$

$$z_h = z_a + \Delta z \left( \frac{c_a}{|\vec{z}|} \right) \quad (\text{B.61})$$

From Fig. B.3:

$$x_1 = |\vec{h}| \cos \delta = h_1 \cos \delta \quad (\text{B.62})$$

$$z_1 = h_1 \cos \theta \quad (\text{B.63})$$

From the dot product relation and Fig. B.3:

$$\vec{z}_x \cdot \vec{h} = |\vec{z}_x| |\vec{h}| \cos \delta = h_1 \cos \delta = x_1 \quad (\text{B.64})$$

$$\vec{z}_z \cdot \vec{h} = |\vec{z}_z| |\vec{h}| \cos \theta = h_1 \cos \theta = z_1 \quad (\text{B.65})$$

Therefore:

$$x_1 = x_x x_h + y_x y_h + z_x z_h \quad (\text{B.66})$$

$$z_1 = x_z x_h + y_z y_h + z_z z_h \quad (\text{B.67})$$

Finally,

$$x_2 = \Delta \tilde{x} - x_1 \quad (\text{B.68})$$

In summary, the computation of the induced velocity contribution of a vortex sheet starts given the following:  $b/2R$ ,  $\gamma_a$ ,  $\gamma_b$ ,  $\vec{a}(x_a, y_a, z_a)$ ,  $\vec{b}(x_b, y_b, z_b)$ ,  $z_m$ , and  $\Delta \tilde{x}$ . First the values of  $|\vec{c}|$ ,  $c_a$ , and  $c_b$  are computed from Eqs. B.36, B.39, and B.40, respectively. Next,  $\vec{i}_x$ ,  $\vec{i}_y$ , and  $\vec{i}_z$  are expressed in the  $x, y, z$  coordinate system. The components of  $\vec{i}_y(x_y, y_y, z_y)$  are computed from Eqs. B.45, B.46, and B.47, respectively. The components of  $\vec{i}_x$  are computed in the order  $z_x, x_x, y_x$  from Eqs. B.48, B.50, and B.51, respectively. The components of  $\vec{i}_z(x_z, y_z, z_z)$  are computed from Eqs. B.54, B.55, and B.56, respectively. Finally, the parameters  $x_1$ ,  $x_2$ , and  $z_1$  are computed from Eqs. B.66, B.68 and B.67, respectively.

Using the above results in Eq. B.22 or in Eq. B.23, the induced velocity ( $\vec{q}_{VS}$ ) in the  $\tilde{x}, \tilde{y}, \tilde{z}$  coordinate system can be computed. To obtain  $\vec{q}_{VS}$  in the  $x, y, z$  coordinate system, the expressions developed above for  $\vec{i}_x$  and  $\vec{i}_z$  are substituted into Eq. B.22 or Eq. B.23. For example, substituting into Eq. B.23 gives:

$$\vec{f}_{vs} = \left(\frac{b}{2R}\right) \left(\frac{\gamma_a}{\Delta \tilde{x}}\right) \left[ (I_1 x_x + I_2 x_z) \vec{i} + (I_1 y_x + I_2 y_z) \vec{j} + (I_1 z_x + I_2 z_z) \vec{k} \right] \quad (B.69)$$

### B.3 Effect of a Viscous Vortex Core

Up to now the effects of a viscous core on a vortex sheet segment have been neglected. These effects are expected to be much smaller for a vortex sheet than for a vortex line because of the spread-out nature of the vortex sheet. However, these effects may still be important and should be investigated. To aid this investigation, the influence of a vortex core is developed for the case of a vortex sheet segment having constant circulation. The "fixed-wing vortex core model", discussed in Section 2.4, is used.

Consider Eq. B.2 specialized for the case of constant circulation

( $\gamma_a = \gamma_b$ ):

$$\vec{f}_{vs} = \left(\frac{b}{2R}\right) \left(\frac{\gamma_a}{\Delta \tilde{x}}\right) \int_{x_2}^{x_1} \left( \frac{\cos \alpha + \cos \beta}{h} \right) \vec{n} d\tilde{x} \quad (B.70)$$

Recall the vortex core circulation distribution from Eq. 2.5:

$$\gamma_c(h) = \frac{h^2}{h^2 + \rho_c^2} \quad (B.71)$$

This  $\gamma_c(h)$  was developed for vortex lines, but since the integral in Eq. B.70 is just the summing up of an infinite number of infinitesimal vortex lines  $\gamma_c(h)$  applies here as well. Recall that  $\gamma_c(h)$  is normalized by the total circulation ( $\gamma_a$ ). From Eqs. B.3 and B.8:

$$\vec{n} = \frac{-z_1 \vec{i} + \tilde{x} \vec{j}}{h} \quad (B.72)$$

Now, putting  $\gamma_c(h)$  inside the integral in Eq. B.70 and using Eq. B.72

$$\vec{q}_{Vs} = \left( \frac{b}{2R} \right) \left( \frac{Y_a}{\Delta X} \right) \int_{x_2}^{x_1} \left( \frac{\cos \alpha + \cos \beta}{h^2 + \rho_c^2} \right) (-z_1 \vec{t}_{\tilde{x}} + \tilde{x} \vec{t}_{\tilde{z}}) d\tilde{x} \quad (\text{B.73})$$

Notice that the only difference which the addition of a vortex core makes is the change from  $h^2$  in the denominator to  $(h^2 + \rho_c^2)$ . This causes a surprisingly large change in the integrated results because a fortunate cancelation no longer occurs.

The integrals  $I_1$  and  $I_2$  of Section B.1 are expanded into  $I_{1a}$ ,  $I_{1b}$ ,  $I_{2a}$ , and  $I_{2b}$  such that:

$$I_1 = I_{1a} + I_{1b} \quad (\text{B.74})$$

$$I_2 = I_{2a} + I_{2b} \quad (\text{B.75})$$

Recalling the definitions of  $\cos \alpha$ ,  $\cos \beta$ , and  $h$  from Eqs. B.6, B.7, and B.3, respectively, the integrals are defined as follows:

$$I_{1a} = \int_{x_2}^{x_1} \left( \frac{c_a}{\sqrt{c_a^2 + \tilde{x}^2 + z_1^2}} \right) \left( \frac{-z_1 d\tilde{x}}{\tilde{x}^2 + z_1^2 + \rho_c^2} \right) \quad (\text{B.76})$$

$$I_{1b} = \int_{x_2}^{x_1} \left( \frac{c_b}{\sqrt{c_b^2 + \tilde{x}^2 + z_1^2}} \right) \left( \frac{-z_1 d\tilde{x}}{\tilde{x}^2 + z_1^2 + \rho_c^2} \right) \quad (\text{B.77})$$

$$I_{2a} = \int_{x_2}^{x_1} \left( \frac{c_a}{\sqrt{c_a^2 + \tilde{x}^2 + z_1^2}} \right) \left( \frac{\tilde{x} d\tilde{x}}{\tilde{x}^2 + z_1^2 + \rho_c^2} \right) \quad (\text{B.78})$$

$$I_{2b} = \int_{x_2}^{x_1} \left( \frac{c_b}{\sqrt{c_b^2 + \tilde{x}^2 + z_1^2}} \right) \left( \frac{\tilde{x} d\tilde{x}}{\tilde{x}^2 + z_1^2 + \rho_c^2} \right) \quad (\text{B.79})$$

There are two cases for each of these integrals  $\rho_c^2 \leq c_a^2$ ,  $c_b^2$  and  $\rho_c^2 \geq c_a^2$ ,  $c_b^2$ .

When  $\rho_c = 0$ , as in Section B.1, only the first case is possible. Recall the definitions of  $S_{1a}$ ,  $S_{1b}$ ,  $S_{2a}$  and  $S_{2b}$  from Eqs. B.14 through B.17, and define the following:

$$z_p \equiv \sqrt{z_{\perp}^2 + \rho_c^2} \quad (\text{B.80})$$

$$c_{pa} \equiv \sqrt{c_a^2 - \rho_c^2} \quad (\text{B.81})$$

$$c_{pb} \equiv \sqrt{c_b^2 - \rho_c^2} \quad (\text{B.82})$$

$$R_{ca} \equiv \sqrt{\rho_c^2 - c_a^2} \quad (\text{B.83})$$

$$R_{cb} \equiv \sqrt{\rho_c^2 - c_b^2} \quad (\text{B.84})$$

The integrals can be evaluated as follows:

$$I_{1a} = \begin{cases} \left( \frac{c_a z_{\perp}}{z_a c_{pa}} \right) \left[ \tan^{-1} \left( \frac{x_2 c_{pa}}{z_p S_{2a}} \right) - \tan^{-1} \left( \frac{x_1 c_{pa}}{z_p S_{1a}} \right) \right], & c_a^2 \geq \rho_c^2 \\ \left( \frac{c_a z_{\perp}}{2 z_p R_{ca}} \right) \ln \left[ \frac{(z_p S_{1a} - x_1 R_{ca})(z_p S_{2a} + x_2 R_{ca})}{(z_p S_{1a} + x_1 R_{ca})(z_p S_{2a} - x_2 R_{ca})} \right], & \rho_c^2 \geq c_a^2 \end{cases} \quad (\text{B.85})$$

$$I_{1b} = \begin{cases} \left( \frac{C_b z_1}{z_p C_{pb}} \right) \left[ \tan^{-1} \left( \frac{x_2 C_{pb}}{z_p S_{2b}} \right) - \tan^{-1} \left( \frac{x_1 C_{pb}}{z_p S_{1b}} \right) \right], & c_b^2 \geq \rho_c^2 \\ \left( \frac{C_b z_1}{2 z_p C_{pb}} \right) \ln \left[ \frac{(z_p S_{1b} - x_1 R_{cb})(z_p S_{2b} + x_2 R_{cb})}{(z_p S_{1b} + x_1 R_{cb})(z_p S_{2b} - x_2 R_{cb})} \right], & \rho_c^2 \geq c_b^2 \end{cases} \quad (\text{B.86})$$

$$I_{2a} = \begin{cases} \left( \frac{C_a}{2 C_{pa}} \right) \ln \left[ \frac{(S_{1a} - C_{pa})(S_{2a} + C_{pa})}{(S_{1a} + C_{pa})(S_{2a} - C_{pa})} \right], & c_a^2 \geq \rho_c^2 \\ \left( \frac{C_a}{R_{ca}} \right) \left[ \tan^{-1} \left( \frac{S_{1a}}{R_{ca}} \right) - \tan^{-1} \left( \frac{S_{2a}}{R_{ca}} \right) \right], & \rho_c^2 \geq c_a^2 \end{cases}$$

(B.87)

$$I_{2b} = \begin{cases} \left( \frac{c_b}{2c_{pb}} \right) \ln \left[ \frac{(S_{1b} - c_{pb})(S_{2b} + c_{pb})}{(S_{1b} + c_{pb})(S_{2b} - c_{pb})} \right], & c_b^2 \geq \rho_c^2 \\ \left( \frac{c_b}{R_{cb}} \right) \left[ \tan^{-1} \left( \frac{S_{1b}}{R_{cb}} \right) - \tan^{-1} \left( \frac{S_{2b}}{R_{cb}} \right) \right], & \rho_c^2 \geq c_b^2 \end{cases} \quad (\text{B.88})$$

Finally  $\vec{q}_{vs}$  can be written as:

$$\vec{q}_{vs} = \left( \frac{b}{2R} \right) \left( \frac{Y_a}{\Delta \tilde{x}} \right) \left[ (I_{1a} + I_{1b}) \vec{\hat{L}}_{\tilde{x}} + (I_{2a} + I_{2b}) \vec{\hat{L}}_{\tilde{z}} \right] \quad (\text{B.89})$$

Notice that the integrals are either  $0/\infty$  or  $(\infty - \infty)/\infty$  when  $c_a^2 = \rho_c^2$  or  $c_b^2 = \rho_c^2$ . To evaluate these cases only,  $I_{1a}$  and  $I_{2a}$  will be considered since  $I_{1b}$  and  $I_{2b}$  have the same behavior. First consider  $I_{1a}$  when  $c_a^2 = \rho_c^2$ , which implies that  $C_{\rho a} = R_{ca} = 0$ . To evaluate this case, use the following expansions for  $\tan^{-1}$  and  $\ln$ :

$$\tan^{-1}(x) = x + \text{HOT} \quad (\text{B.90})$$

$$\ln(1+x) = x + \text{HOT} \quad (\text{B.91})$$

Using these expansions on the  $c_a^2 \geq \rho_c^2$  and the  $\rho_c^2 \geq c_a^2$  expressions for  $I_{1a}$  gives the same answer in both cases, when  $c_a^2 = \rho_c^2$ :

$$I_{1a} = c_a z_{\perp} \left( \frac{x_2 S_{1a} - x_1 S_{2a}}{S_{1a} S_{2a} z_{\rho}^2} \right) \quad (\text{B.92})$$

To evaluate  $I_{2a}$  when  $c_a^2 = \rho_c^2$ , a different expansion for  $\tan^{-1}$  is used:

$$\tan^{-1}(x) = \frac{\pi}{2} - \frac{1}{x} + \text{HOT} \quad (\text{B.93})$$

Again both the  $c_a^2 \geq \rho_c^2$  and the  $\rho_c^2 \geq c_a^2$  expressions give the same answer, when  $c_a^2 = \rho_c^2$ :

$$I_{za} = \left( \frac{c_a}{s_{za}} - \frac{c_a}{s_{ia}} \right) \quad (\text{B.94})$$

## APPENDIX C

### VELOCITY INDUCED BY A CURVED VORTEX LINE SEGMENT

#### C.1 Computation of the Induced Velocity for a Given

##### Arc Length and Radius of Curvature

Consider a circular arc vortex line segment of arc length  $\Delta\theta_c$  and radius of curvature  $\rho_{VL}$  (nonD by R). Assume the vortex line has a viscous vortex core of radius  $\rho_c$  (nonD by R). Label the ends of the vortex line segment points  $P_\eta$  and  $P_a$ . Now consider the computation of the induced velocity at point  $P_\eta$ . Lamb in article 163 of [35] develops an expression for the self-induced velocity of a vortex ring. To solve the problem at hand, Lamb's expression can be used by subtracting the contribution from all of the ring except the segment between point  $P_\eta$  and  $P_a$ .

Assuming a circulation  $\Gamma$  and introducing different notation, Lamb's expression can be written:

$$q_{VR} = \frac{\Gamma}{4\pi R \rho_{VL}} \left[ \ln \left( \frac{8\rho_{VL}}{\rho_c} \right) - \frac{1}{4} \right] \quad (C.1)$$

It should be noted that Lamb developed this expression assuming  $\rho_c \ll \rho_{VL}$ . By symmetry, the induced velocity at point  $P_\eta$  due to half of the vortex ring starting at point  $P_\eta$  and ending  $180^\circ$  away is half of the result in Eq. C.1. This corresponds to the case  $\Delta\theta_c = \pi (180^\circ)$  for the curved vortex line segment problem. With circulation  $\gamma (\gamma = \Gamma/2\pi b\Omega R)$ , the induced velocity (nondimensional by tip speed) for the case  $\Delta\theta_c = \pi$  can be written as:

$$q_{CVL}(\Delta\theta_c = \pi) = \gamma \left( \frac{b}{2R} \right) \left( \frac{1}{\rho_{VL}} \right) \left[ \ln \left( \frac{8\rho_{VL}}{\rho_c} \right) - \frac{1}{4} \right] \quad (C.2)$$

To find  $q_{CVL}$  for a general  $\Delta\theta_c$ , the induced velocity due to the part of the ring between  $\theta_c = \Delta\theta_c$  and  $\theta_c = \pi$  must be computed. From Eq. A.6 in Appendix A, the Biot Savart Relation can be written:

$$dq_{RVL} = \gamma \left( \frac{b}{2R} \right) \frac{\sin \theta \, ds}{r^2} \quad (C.3)$$

where  $ds$  is the vortex line element at  $\theta_c$  (nonD by  $R$ ),  $r$  is the distance from point  $P_\eta$  to  $ds$  (nonD by  $R$ ),  $\theta$  is the angle between the tangent to the circular arc at  $ds$  and the line  $r$ ,  $\gamma$  is the circulation at  $ds$  (nonD by  $2\pi b\Omega R$ ), and  $b/2R$  is the rotor blade semichord over twice the rotor radius. In Fig. C.1 draw a tangent to the circular arc vortex line at  $ds$ . Drop a perpendicular of length  $h$  (nonD by  $R$ ) from point  $P_\eta$  to the tangent. Now it can be seen that:

$$\sin \theta = \frac{h}{r} \quad (C.4)$$

In Fig. C.1 draw a radius of length  $\rho_{VL}$  (nonD by  $R$ ) from the center of curvature to  $ds$ . Drop a perpendicular from point  $P_\eta$  to the radius. Now observe that the length of this perpendicular is  $\rho_{VL} \sin \theta_c$ . Further, observe that this perpendicular is parallel to the tangent which implies that:

$$h = \rho_{VL} - \rho_{VL} \cos \theta_c \quad (C.5)$$

Now from Fig. C.1:

$$r^2 = h^2 + \rho_{VL}^2 \sin^2 \theta_c \quad (C.6)$$

Or, substituting for  $h$ :

$$r = \rho_{VL} \sqrt{2(1 - \cos \theta_c)} \quad (C.7)$$

Substituting Eqs. C.5 and C.7 into Eq. C.4:

$$\sin \theta = \sqrt{\frac{1 - \cos \theta_c}{2}} \quad (C.8)$$

Writing  $ds$  in terms of  $\theta_c$ :

$$ds = \rho_{VL} d\theta_c \quad (C.9)$$

Substituting into Eq. C.3 and integrating from  $\theta_c = \Delta\theta_c$  to  $\theta_c = \pi$ :

$$q_{rVL} = \gamma \left( \frac{b}{2R} \right) \int_{\Delta\theta_c}^{\pi} \left[ \sqrt{\frac{1 - \cos \theta_c}{2}} \frac{\rho_{VL}}{\rho_{VL}^2 (2)(1 - \cos \theta_c)} \right] d\theta_c \quad (C.10)$$

Recall the trig identity:

$$\sin\left(\frac{\theta_c}{2}\right) = \sqrt{\frac{1 - \cos \theta_c}{2}} \quad (C.11)$$

Therefore:

$$q_{RVL} = \gamma \left(\frac{b}{2R}\right) \left(\frac{1}{4\rho_{VL}}\right) \int_{\Delta\phi}^{\pi} \frac{d\theta_c}{\sin(\theta_c/2)} \quad (C.12)$$

$$q_{RVL} = \gamma \left(\frac{b}{2R}\right) \left(\frac{1}{2\rho_{VL}}\right) \left[ -\ln \tan\left(\frac{\Delta\theta_c}{4}\right) \right] \quad (C.13)$$

Now subtracting Eq. C.13 from Eq. C.2:

$$q_{CVL} = \gamma \left(\frac{b}{2R}\right) \left(\frac{1}{2\rho_{VL}}\right) \left\{ \ln \left[ \left(\frac{8\rho_{VL}}{\rho_c}\right) \tan\left(\frac{\Delta\theta_c}{4}\right) \right] - \frac{1}{4} \right\} \quad (C.14)$$

Equation C.14 is the desired expression for the induced velocity in terms of the arc length and the radius of curvature.

## C.2 Determination of the Arc Length and Radius of Curvature

To determine  $\Delta\theta_c$  and  $\rho_{VL}$ , the center of curvature must be found. Recall that three points determine a circle. On the tip vortex there is always at least one vortex line segment downstream of point  $P_\eta$  and at least one segment upstream. Label the ends of these adjacent vortex line segments points  $P_\eta$  and  $P_a$  and points  $P_b$  and  $P_\eta$ , respectively (Fig. C.2). Now the three points  $P_a$ ,  $P_\eta$ , and  $P_b$  can be used to define a circular arc.

Define  $\vec{a}_c$  and  $\vec{b}_c$  as vectors (nonD by R) from point  $P_\eta$  to points  $P_a$  and  $P_b$ , respectively. Define  $a_c$  and  $b_c$  as the magnitudes of  $\vec{a}_c$  and  $\vec{b}_c$ , respectively. Construct radii of length  $\rho_{VL}$  from the center of curvature to points  $P_\eta$ ,  $P_a$ , and  $P_b$  (Fig. C.2). Define the angles  $\alpha_c$ ,  $\beta_c$ ,  $\Delta\theta_a$ , and  $\Delta\theta_b$  as shown in Fig. C.2. Drop perpendiculars from the center of curvature to  $\vec{a}_c$  and  $\vec{b}_c$  in Fig. C.2.

Notice that these perpendiculars are actually perpendicular bisectors since  $\vec{a}_c$  and  $\vec{b}_c$  are the bases of a pair of isosceles triangles having sides  $\rho_{VL}$  long. Therefore:

$$\rho_{VL} \cos \alpha_c = \frac{a_c}{2} \quad (C.15)$$

$$\rho_{VL} \cos \beta_c = \frac{b_c}{2} \quad (C.16)$$

$$\rho_{VL} \sin \alpha_c = \sqrt{\rho_{VL}^2 - \left(\frac{a_c}{2}\right)^2} \quad (C.17)$$

$$\rho_{VL} \sin \beta_c = \sqrt{\rho_{VL}^2 - \left(\frac{b_c}{2}\right)^2} \quad (C.18)$$

Recall the trig identity:

$$\cos \beta_c = \cos(\alpha_c + \beta_c - \alpha_c) = \cos(\alpha_c + \beta_c) \cos \alpha_c + \sin(\alpha_c + \beta_c) \sin \alpha_c \quad (C.19)$$

Therefore, using Eqs. C.15, C.16, and C.17:

$$b_c = 2\rho_{VL} \cos \beta_c = a_c \cos(\alpha_c + \beta_c) + \sin(\alpha_c + \beta_c) \sqrt{4\rho_{VL}^2 - a_c^2} \quad (C.20)$$

Solving for  $\rho_{VL}$ :

$$\rho_{VL} = \frac{1}{2} \sqrt{a_c^2 + \left[ \frac{b_c - a_c \cos(\alpha_c + \beta_c)}{\sin(\alpha_c + \beta_c)} \right]^2} \quad (C.21)$$

Recall the dot and cross product relations:

$$\vec{a}_c \cdot \vec{b}_c = a_c b_c \cos(\alpha_c + \beta_c) \quad (C.22)$$

$$|\vec{a}_c \times \vec{b}_c| = a_c b_c \sin(\alpha_c + \beta_c) \quad (C.23)$$

Now substituting into Eq. C.21:

$$\rho_{VL} = \frac{a_c}{2} \sqrt{1 + \frac{(b_c^2 - \vec{a}_c \cdot \vec{b}_c)^2}{|\vec{a}_c \times \vec{b}_c|^2}} \quad (C.24)$$

Now it is necessary to find expressions for  $\tan(\Delta\theta_a/4)$  and  $\tan(\Delta\theta_b/4)$ . Recall the trig identity:

$$\tan\left(\frac{\Delta\theta_a}{4}\right) = \frac{1 - \cos\left(\frac{\Delta\theta_a}{2}\right)}{\sin\left(\frac{\Delta\theta_a}{2}\right)} \quad (C.25)$$

Observe in Fig. C.2 that:

$$\cos\left(\frac{\Delta\theta_a}{2}\right) = \sin \alpha_c \quad (C.26)$$

$$\sin\left(\frac{\Delta\theta_a}{2}\right) = \cos \alpha_c \quad (C.27)$$

Substituting into Eq. C.25 and multiplying by  $(2\rho_{VL}/2\rho_{VL})$ :

$$\tan\left(\frac{\Delta\theta_a}{4}\right) = \frac{2\rho_{VL} - 2\rho_{VL} \sin \alpha_c}{2\rho_{VL} \cos \alpha_c} \quad (C.28)$$

Substituting Eqs. C.15 and C.17 into Eq. C.28:

$$\tan\left(\frac{\Delta\theta_a}{4}\right) = \frac{2\rho_{VL} - \sqrt{4\rho_{VL}^2 - a_c^2}}{a_c} \quad (C.29)$$

By a similar process an expression can be developed for  $\tan(\Delta\theta_b/4)$ :

$$\tan\left(\frac{\Delta\theta_b}{4}\right) = \frac{2\rho_{VL} - \sqrt{4\rho_{VL}^2 - b_c^2}}{b_c} \quad (C.30)$$

Define the  $\ln$  expression in Eq. C.14 for  $\Delta\theta_a$  and  $\Delta\theta_b$  as:

$$AL \equiv \frac{8\rho_{VL}}{\rho_c} \tan\left(\frac{\Delta\theta_a}{4}\right) \quad (C.31)$$

$$BL \equiv \frac{8\rho_{VL}}{\rho_c} \tan\left(\frac{\Delta\theta_b}{4}\right) \quad (C.32)$$

Substituting Eqs. C.24 and C.30 into Eq. C.31:

$$AL = \frac{4a_c}{\rho_c |\vec{a}_c \times \vec{b}_c|^2} \left[ |\vec{a}_c \times \vec{b}_c|^2 + (b_c^2 - \vec{a}_c \cdot \vec{b}_c)^2 - (b_c^2 - \vec{a}_c \cdot \vec{b}_c) \sqrt{|\vec{a}_c \times \vec{b}_c|^2 + (b_c^2 - \vec{a}_c \cdot \vec{b}_c)^2} \right] \quad (C.33)$$

To develop a similar expression for BL, note that an alternative expression for  $v_L$  can be developed the same way Eq. C.24 was developed, but starting from:

$$\cos \alpha_c = \cos (\alpha_c + \beta_c - \beta_c) \quad (C.34)$$

instead of from Eq. C.19. The result is:

$$\rho_{v_L} = \frac{b_c}{2} \sqrt{1 + \frac{(a_c^2 - \vec{a}_c \cdot \vec{b}_c)^2}{|\vec{a}_c \times \vec{b}_c|^2}} \quad (C.35)$$

Substituting Eqs. C.29 and C.35 into Eq. C.32:

$$BL = \frac{4b_c}{\rho_c |\vec{a}_c \times \vec{b}_c|^2} \left[ |\vec{a}_c \times \vec{b}_c|^2 + (a_c^2 - \vec{a}_c \cdot \vec{b}_c)^2 - (a_c^2 - \vec{a}_c \cdot \vec{b}_c) \sqrt{|\vec{a}_c \times \vec{b}_c|^2 + (a_c^2 - \vec{a}_c \cdot \vec{b}_c)^2} \right] \quad (C.36)$$

To find the direction of the induced velocity  $\vec{q}_{CVL}$ , notice that points  $P_a$ ,  $P_\eta$  and  $P_b$  form a plane and that the induced velocity must be perpendicular to this plane. Therefore, the induced velocity contributions of both  $\Delta\theta_a$  and  $\Delta\theta_b$  [ $\vec{q}_{CVL}(\Delta\theta_a + \Delta\theta_b)$ ] are parallel to  $\vec{a}_c \times \vec{b}_c$ . Define the circulations (nonD by  $2\pi b \Omega R$ ) of the segments  $\Delta\theta_a$  and  $\Delta\theta_b$  as  $\gamma_a$  and  $\gamma_b$ , respectively. The signs of  $\gamma_a$  and  $\gamma_b$  imply  $\vec{q}_{CVL}(\Delta\theta_a + \Delta\theta_b)$  in the positive  $\vec{a}_c \times \vec{b}_c$  direction (i.e., into the paper in Fig. C.2). Now multiplying  $q_{CVL}(\Delta\theta_a + \Delta\theta_b)$  by  $(\vec{a}_c \times \vec{b}_c) / (|\vec{a}_c \times \vec{b}_c|)$  to obtain  $\vec{q}_{CVL}(\Delta\theta_a + \Delta\theta_b)$  and using Eqs. C.14, C.24, C.31, and C.32:

$$\vec{q}_{CVL}(\Delta\theta_a + \Delta\theta_b) = \left\{ \frac{\gamma_a [\ln(AL) - 1/4] + \gamma_b [\ln(BL) - 1/4]}{a_c \sqrt{|\vec{a}_c \times \vec{b}_c|^2 + (b_c^2 - \vec{a}_c \cdot \vec{b}_c)^2}} \right\} \left( \frac{b}{2R} \right) (\vec{a}_c \times \vec{b}_c) \quad (C.37)$$

In summary, to compute  $\vec{q}_{CVL}(\Delta\theta_a + \Delta\theta_b)$  given  $\vec{a}_c$ ,  $\vec{b}_c$ ,  $\gamma_a$ ,  $\gamma_b$ ,  $\rho_c$ , and  $b/2R$ , use Eqs. C.33, C.36, and C.37.

## APPENDIX D

### TIP VORTEX CORE MODELS

#### D.1 Introduction

The simple solid body rotation vortex core model is adequately described in Section 2.4. This appendix documents the two more complex vortex core models in more detail than is appropriate for Section 2.4. In addition, the Betz theory of wing-wake roll-up is applied to both the fixed-wing and rotary-wing cases.

#### D.2 Fixed-Wing Vortex Core Model

The model normally used for all straight wake elements is the "fixed-wing vortex core model" (FWVCM). This model is based on measurements of the properties of tip vortices in the wake of fixed-wing and wind-tunnel models [36,37,38, 43]. The data from these references, which is used here, covers rectangular planform wings with aspect ratios from 4.2 to 6, Reynolds numbers from  $3 \times 10^5$  to  $7 \times 10^6$ , and Mach numbers from 0.08 to 0.5. The data given in the references often covers a range of distances downstream from the wing. When it is possible, the data used here is for downstream distances (or times) which are typical of the first blade-vortex interaction on multibladed helicopter rotors.

The data in [36,37,38,43] contains some plots of tangential induced velocity ( $V_\theta$ ) vs. radial distance from the vortex centerline  $\rho$ . The primary data, however, is peak tangential induced velocity  $V_\theta^*$  and the radius at which this  $V_\theta^*$  occurs. This radius is, by definition, the vortex-core radius ( $\rho_c$ , when normalized by the wing span  $R$ ). The first step in constructing a vortex-core model is to find expressions for  $V_\theta^*$  and  $\rho_c$ . Due to the limited range of aspect ratio, it is not possible to decide from the data whether  $\rho_c$  is a function of wing span  $R$  or wing chord  $c$ . Intuitively the chord seems more reasonable. On this basis,  $\rho_c$  varies from 2.5% of the chord to 6.3% of the chord in the data selected from [36, 37, 38, 43]. A value of 5% of the chord is, therefore used for  $\rho_c$  in the standard FWVCM; however,  $\rho_c$  is a parameter which can be varied to suit various theories.

The peak velocity  $V_{\theta}^*$  can be normalized by  $\Gamma/(4\pi R\rho_c)$ , where  $\Gamma$  is the tip vortex circulation. The problem with this normalization of  $V_{\theta}^*$  is that  $\Gamma$  is difficult to measure accurately. A much easier quantity to measure is the lift coefficient  $C_L$ . Assuming that the tip vortex circulation  $\Gamma$  is equal to the average bound circulation:

$$\rho V \Gamma = \frac{1}{2} \rho V^2 c C_L \quad (D.1)$$

where  $\rho$  = air density,  $V$  = wind speed, and  $c$  = wing chord. This allows the normalizing factor to be written in terms of  $C_L$ :

$$\frac{\Gamma}{4\pi R\rho_c} = \frac{c V C_L}{8\pi R\rho_c} \quad (D.2)$$

In Section D.4, a theory is presented which says that  $\Gamma$  should be equal to the maximum bound circulation instead of the average. For a typical rectangular wing case this increases the normalizing factor based on  $C_L$  by about 7%, which is not significant, given the scatter in the data reviewed here.

Using either the normalizing factor based on  $\Gamma$  or based on  $C_L$ , as appropriate, selected  $V_{\theta}^*$  data has been normalized. The resulting values range from 0.84 to 1.39 or from 0.78 to 1.30, depending upon whether the average  $\Gamma$  or the peak  $\Gamma$  is used. A value of 1.0 is chosen as representative and convenient. Therefore:

$$V_{\theta}^* = \frac{\Gamma}{4\pi R\rho_c} \quad (D.3)$$

The peak velocity  $V_{\theta}^*$  and the location of the peak  $\rho_c$  have been determined. The next step is to fit a smooth curve through this peak which fits into Biot Savart for large  $\rho$  and which is linear for small  $\rho$ . A simple function which does this is:

$$V_{\theta} = \frac{\Gamma}{4\pi R\rho_c} \left( \frac{2\rho}{1 + \rho^2} \right) \quad (D.4)$$

This implies a radial circulation distribution:

$$\gamma_c(\rho) = \left( \frac{\rho^2}{1 + \rho^2} \right) \quad (D.5)$$

In Fig. D.1, this FWVCM function (Eq. D.4) is compared with measured data from Fig. 6 of [43] and with Biot Savart. For this plot, the measured values of vortex core radius (5.3% chord) and normalized  $V_\theta^*$  (0.968) are used, instead of the standard values (5% and 1.0, respectively). This makes the peaks match between the measured data and the FWVCM, which allows a direct comparison of the shape of the curves.

The FWVCM function can be seen to approach Biot Savart faster than the measured data. A more complicated function could be found to improve this; however, given the uncertainty in  $\rho_c$  and  $V_\theta^*$ , it is not worth the extra expense. The measured data is above Biot Savart for large  $\rho$ , in Fig. D.1. This implies that the  $\Gamma$  used is too small. This  $\Gamma$  is reduced by a factor of 0.968 from the  $\Gamma$  of Eq. D.1 in order to match peak heights. Furthermore, as mentioned above, the  $\Gamma$  of Eq. D.1 may be 7% too small. Finally, the measured curve in Fig. D.1 is a mean drawn through the actual data points and may not be completely accurate.

In summary, the fixed-wing vortex core model is a very simple model based on fixed-wing tip vortex measurements. It is much more realistic than the solid-body rotation model which has an induced velocity peak twice as high. Finally, it is about as complicated a model as can be justified, given the variations in the measured data and the lack of understanding of these variations.

### D.3 Rotary-Winged Vortex Core Model

Recently, detailed measurements of tip vortex properties for a rotor at full-scale Mach and Reynolds numbers were published in [39]. This data shows a vortex core radius almost an order of magnitude smaller than the fixed-wing data, with a peak induced velocity which is nearly the same. This implies a very different tip vortex radial circulation distribution for rotors compared to fixed wings. A different vortex core model, the "rotary-wing vortex core model" (RWVCM), is used to represent this data.

The data in [39] is presented as a function of the age of the tip vortex measured in degrees of azimuth angle. Since we are primarily concerned with the properties of the tip vortex when it first interacts with the following

blade, only the data for an age of about 100° is considered. This data shows an average vortex-core radius ( $\rho_c$ ) of about 0.008 chords and an average peak tangential induced velocity ( $V_\theta^*$ ) of about  $0.20(\Gamma/4\pi R\rho_c)$ , where  $\rho_c$  is normalized by R. A typical plot of tangential induced velocity vs. radius is given in Fig. 13 of [39]. A function which approximates this measured data outboard of the vortex core is:

$$V_\theta = \frac{V_\theta^*}{\rho} \left[ 10 - 9 e^{-.075(\rho-1)} \right] \quad (D.6)$$

where  $\rho$  is normalized by the vortex core radius  $\rho_c$ . This function is compared with the measured data and with the Biot-Savart relation in Fig. D.2. A function with a maximum at  $\rho = 1$  would be desirable but the function of Eq. D.6 is satisfactory. The induced velocity inside the vortex core can be represented by Eq. D.5 multiplied by 0.2 to get the correct peak height. This gives the following expression for  $V_\theta$ :

$$V_\theta = \begin{cases} \frac{\Gamma}{4\pi R\rho_c} \left( \frac{0.4\rho}{1+\rho^2} \right) & , \rho \leq 1.0 \\ \frac{\Gamma}{4\pi R\rho_c} \left( \frac{2}{\rho} \right) \left[ 1.0 - 0.9 e^{-.075(\rho-1)} \right] & , \rho \geq 1.0 \end{cases} \quad (D.7)$$

Using this expression for  $V_\theta$  the radial distribution of vortex core circulation  $\gamma_c(\rho)$  can be determined.

$$\gamma_c(\rho) = \begin{cases} \left( \frac{0.2\rho^2}{1+\rho^2} \right) & , \rho \leq 1.0 \\ \left[ 1.0 - 0.9 e^{-.075(\rho-1)} \right] & , \rho \geq 1.0 \end{cases} \quad (D.8)$$

Recently, some preliminary measurements of model rotor tip vortex properties have been published [44]. These measurements show tip vortex properties closer to the fixed-wing data [36,37,38] than to the rotor-wing data [39]. In addition, [44] refers to [45], which contains measurements of tip vortex properties for a full-scale rotor. The measurements in [45] are also closer to

the fixed-wing measurements. This casts some doubt on the validity of the RWVCM, which is another reason the RWVCM remains experimental while the FWVCM is standard.

#### D.4 Betz Theory for Tip Vortex Roll-Up

Betz [41] has developed a theory for the roll-up of the trailing vortex wake of a wing. This theory has been simplified and extended by Donaldson, Rossow, et al. [46,47,48]. The net result is a method for computing the radial distribution of circulation in the final rolled-up wake  $[\Gamma_c(r)]$ , given the spanwise distribution of bound circulation on the wing  $[\Gamma_b(y)]$ . Define the centroid of all bound circulation outboard of any spanwise station  $y$  as  $\bar{y}$ :

$$\bar{y} = \frac{\int_y^1 \frac{d\Gamma_b(\xi)}{d\xi} \xi d\xi}{-\Gamma_b(y)} \quad (D.9)$$

where  $y$  and  $\bar{y}$  are normalized by the span. Then let the radial coordinate of the rolled-up vortex (normalized by span) be  $r$ . The theory says that when:

$$r = \bar{y} - y \quad (D.10)$$

then:

$$\Gamma_c(r) = \Gamma_b(y) \quad (D.11)$$

In other words, the total circulation within a radius  $r$  of the center of the rolled-up vortex core  $[\Gamma_c(r)]$  is the same as the bound circulation on the wing at spanwise station  $y$   $[\Gamma_b(y)]$ , provided that Eq. D.10 is satisfied.

As is written above, the theory applies to the roll-up into a tip vortex of the wake outboard of spanwise station  $y_m$  on the wing where the magnitude of the slope of the bound circulation  $|d\Gamma_b(y)/dy|$  decreases monotonically from a maximum at the wing tip to a minimum at  $y_m$ . The theory for more complicated  $\Gamma_b(y)$  functions and for inboard wake roll-up is given by Donaldson [46]. Since this is an inviscid theory, it cannot be expected to predict a viscous phenomenon like the vortex core radius. Indeed, given the required nature of  $\Gamma_b(y)$ , the induced velocity will rise monotonically to a peak as  $r$  goes from

$+\infty$  to  $0+$ . It will then jump to an equal peak of opposite sign at  $r = 0-$  and decrease monotonically as  $r$  goes to  $-\infty$ . The magnitude of the induced velocity peak is related to the slope of  $\Gamma_b(y)$  at the wing tip and has nothing to do with viscosity. Thus, this theory cannot be expected to predict either the vortex core radius  $\rho_c$  or the magnitude of the peak tangentially induced velocity  $V_\theta^*$ . The theory may be able to predict the reduction of the measured tangentially induced velocity  $V_\theta$  below that predicted by Biot Savart for some of the tip vortex outside of the vortex core.

To apply this theory to rotors, replace the word wing with rotor blade, replace the word spanwise with radial, replace  $y$  and  $y_m$  with  $\eta$  and  $\eta_m$ , and consider an appropriate  $\Gamma_b(\eta)$ . An obvious difference between wings and rotors is the location of  $y_m$ . For simply loaded wings, the minimum  $|d\Gamma_b(y)/dy|$  would be expected to correspond with the maximum  $\Gamma_b(y)$  and be at the center of the wing ( $y_m = 0.5$ ). For rotors, the average around the azimuth of the minimum  $|d\Gamma_b(\eta)/d\eta|$  also corresponds to the maximum  $\Gamma_b(\eta)$ , but this maximum is located outboard of the middle of the rotor blade, typically  $\eta_m = 0.85 - 0.95$ .

To simplify the computations, define a coordinate  $x$  which runs from  $x = 1.0$  at  $\eta = \eta_m$  to  $x = 0.0$  at  $\eta = 1.0$ , the blade tip. This means that:

$$x(1 - \eta_m) = 1 - \eta \quad (D.12)$$

Define a new radial coordinate from the center of the tip vortex normalized by  $(1 - \eta_m)R$  instead of  $R$ :

$$\rho_x \equiv r / (1 - \eta_m) \quad (D.13)$$

Define a new bound circulation distribution  $\gamma_b(x)$  and a new radial tip vortex circulation distribution  $\gamma_c(\rho_x)$ , both normalized by the total tip vortex circulation  $\Gamma$ .

$$\gamma_b(x) \equiv \Gamma_b(\eta) / \Gamma \quad (D.14)$$

$$\gamma_c(\rho_x) \equiv \Gamma_c(r) / \Gamma \quad (D.15)$$

Note that  $\Gamma$  will be equal to the  $\Gamma_b(\eta)$  when  $\eta = \eta_m$ .

$$\Gamma = \Gamma_b(\gamma_m) \quad (D.16)$$

Now introducing the new variables and combining Eqs. D.9 and D.10:

$$\rho_x(x) = \frac{x\gamma_b(x) + \int_x^0 \frac{d\gamma_b(\xi)}{d\xi} \xi d\xi}{\gamma_b(x)} \quad (D.17)$$

The Biot Savart relation gives the tangential induced velocity  $V_\theta$  as a function of radius  $r$  as:

$$V_\theta = \frac{\Gamma_c(r)}{2\pi R r} \quad (D.18)$$

Introducing the new notation:

$$V_\theta = \frac{\Gamma}{2\pi R (1-\gamma_m)} \frac{\gamma_c(\rho_x)}{\rho_x(x)} \quad (D.19)$$

Recalling Eqs. D.11, D.14, and D.15:

$$V_\theta = \frac{\Gamma}{2\pi R (1-\gamma_m)} \frac{\gamma_b(x)}{\rho_x(x)} \quad (D.20)$$

If, for a given  $\gamma_b(x)$ , one is able to invert  $\rho_x(x)$  to obtain  $x(\rho_x)$ , then  $\gamma_c(\rho_x)$  can be found by substitution of  $x(\rho_x)$  into  $\gamma_b(x)$ . Normally, this is not practical and Eq. D.20 must be used. Equation D.20 gives  $V_\theta(x)$ , not  $V_\theta(\rho_x)$ . To obtain  $V_\theta(\rho_x)$ , the functions  $V_\theta(x)$  and  $\rho_x(x)$  must be tabulated or cross-plotted. Finally,  $V_\theta(r)$  is obtained by the use of Eq. D.13.

Define a normalized tangentially induced velocity  $v(\rho_x)$ :

$$v(\rho_x) \equiv \frac{\gamma_b(x)}{\rho_x(x)} \quad (D.21)$$

This  $v(\rho_x)$  can be plotted vs.  $\rho_x(x)$  to obtain a normalized version of the  $v_\theta$  vs.  $r$  plot. The interesting thing about this is that all of the effects of changes in  $\gamma_b(x)$  are in  $v(\rho_x)$ , while all of the effects of changes in  $\eta_m$  are in the normalizing factors for  $v(\rho_x)$  and  $\rho_x(x)$ .

For an ideal, concentrated vortex Biot Savart gives:

$$v(\rho_x) = 1.0 / \rho_x(x) \quad (D.22)$$

By definition:  $\gamma_b(x) = 1.0$  for  $x \geq 1.0$ ; therefore the Biot Savart value of  $v(x)$  applies for all values of  $\rho_x(x) > \rho_x(1.0)$ , no matter what  $\gamma_b(x)$  is used. For the classic elliptical spanwise loading:

$$\gamma_b(\eta) = \sqrt{1 - \eta^2} \quad (D.23)$$

which implies:

$$\gamma_b(x) = \sqrt{2x - x^2} \quad (D.24)$$

This, in turn, gives:

$$\rho_x(x) = \frac{\frac{\pi}{2} - \sin^{-1}(1-x)}{2\sqrt{2x - x^2}} - \left(\frac{1-x}{2}\right) \quad (D.25)$$

Another  $\gamma_b(x)$  which might be used to approximate the spanwise loading on a rectangular wing is:

$$\gamma_b(x) = (1-\delta) + \delta \sqrt{2x - x^2} \quad (D.26)$$

This gives:

$$\rho_x(x) = \frac{\frac{\delta\pi}{2} - \delta \sin^{-1}(1-x) + (1-\delta)(1+x)}{2\sqrt{2x - x^2}} - \left(\frac{1-x}{2}\right) \quad (D.27)$$

Figure D.3 shows the  $v(\rho_x)$  vs.  $\rho_x(x)$  plots for these three  $\gamma_b(x)$  (Eqs. D.22, D.24, and D.26). The value of  $\delta = 0.4$  used in Eq. D.26 represents a rectangular wing as will be discussed later.

Now consider the effect of going from  $\eta_m = 0.5$  (fixed wing) to  $\eta_m = 0.95$  (rotary wing in hover). Using Eq. D.13 for a given  $r$ : for  $\eta_m = 0.5$ ,  $\rho_x = 2r$  and for  $\eta_m = 0.95$ ,  $\rho_x = 20r$ . From Fig. D.3 we see that  $v(x)$  increases as  $\rho_x(x)$  decreases. Thus,  $v(\rho_x)$  increases as  $\eta_m$  decreases, for a given  $r$  and  $\gamma_b(x)$ . Let  $V_\theta = K v(\rho_x)$  for  $\eta_m = 0.50$ , where  $K$  is a constant. Then, for the same  $r$  and  $\gamma_b(x)$ ,  $V_\theta = 10K v(10\rho_x)$  for  $\eta_m = 0.95$ . The question is: which is greater  $Kv(\rho_x)$  or  $10Kv(10\rho_x)$ ? Consider the case when they are equal:

$$K v(\rho_x) = 10 K v(10\rho_x) \quad (D.28)$$

It is easily shown that Eq. D.22 (the Biot Savart case) satisfies Eq. D.28. Clearly, for any  $v(\rho_x)$  which rises less rapidly with decreasing  $\rho_x$ , Eq. D.22 will result in:

$$K v(\rho_x) < 10 K v(10\rho_x) \quad (D.29)$$

For the type of  $\gamma_b(x)$  required by this restricted version of the theory, the  $\gamma_c(\rho_x)$  are all monotonically decreasing functions going from  $\gamma_c(\rho_x(1.0)) = 1.0$  to  $\gamma_c(0.0) = 0.0$ . Thus  $v(\rho_x)$  is always less steep than Eq. D.22 for  $\rho_x(x) < \rho_x(1.0)$ , and Eq. D.29 applies. In general, therefore, if  $\gamma_b(x)$  is fixed and  $\eta_m$  is allowed to change, then at any given  $r < (1 - \eta_m) \rho_x(1.0)$ ,  $V_\theta$  will increase as  $\eta_m$  increases.

Flight test data [49,50,51] shows that the radial peak of the zeroth harmonic (azimuthal average) of the bound circulation on a helicopter rotor blade varies from about  $\eta_m = 0.85$  at moderate advance ratios to about  $\eta_m = 0.95$  at hover. Data was only taken at a limited number of radial stations in these tests:  $\eta = 0.25, 0.40, 0.55, 0.75, 0.85, 0.90, 0.95$  for [49,50] and  $\eta = 0.40, 0.75, 0.85, 0.95, 0.98$  for [51]. This limited data is enough to estimate  $\eta_m$  but not enough to define the shape of  $\gamma_b(x)$ .

For fixed wings, Fig. 3 of [42] gives the spanwise airload distribution for one of the cases later repeated in [37] and quoted here in Table I. For this case  $\eta_m = 0.7$ , assuming the oscillations near the wing tip are faired out, as is done in [48]. Fairing out these oscillations near the tip amounts to assuming that the various independent vortices generated by these oscillations will ultimately all rollup into one main vortex. Betz theory ignores

this possibility, so the only way to achieve this final result is to eliminate the oscillations.

Looking back at Fig. 8, we see that  $V_\theta$  from the FWVCM is greater than the  $V_\theta$  from the RWVCM for  $\rho > 1.0$ . This area outside of the core ( $\rho > 1.0$ ) is where the Betz model should work. The RWVCM is based on hovering rotor data, and from the discussion above, should have  $\eta_m = 0.95$ . Similarly, the FWVCM data should have an  $\eta_m$  between 0.5 and 0.7. Thus,  $V_\theta$  is increasing while  $\eta_m$  is decreasing. This implies that the  $\gamma_b(x)$  must be very much more tip-loaded for the fixed-wing case compared to the rotary-wing case in order to overcome the effect of  $\eta_m$  on  $V_\theta$ . Another possibility is that the oscillations in the fixed-wing data should not be faired, in which case  $\eta_m = 0.98$ . This will be examined below.

For the rotary-wing case, the measured data of Fig. 13 in [39] is plotted in Fig. D.4. For comparison, the Biot Savart value of  $V_\theta$  (also from [39]) and the Betz model value of  $V_\theta$  for an elliptical  $\gamma_b(x)$  are also plotted. The agreement is reasonable but the use of an elliptical  $\gamma_b(x)$  is questionable. The data in [51] shows that the bound circulation at  $\eta = 0.98$  is about 92% of the bound circulation at  $\eta = 0.95$ . The elliptical  $\gamma_b(x)$  gives only 80% at  $\eta = 0.98$ . If  $\gamma_b(x)$  from Eq. D.26 is used, a  $\delta = 0.4$  is needed to get the 92%. The  $v(\rho_x)$  for this  $\gamma_b(x)$  is compared with Biot Savart and with an elliptical  $\gamma_b(x)$  in Fig. D.3. Comparing this plot with Fig. D.4, it is clear that this  $\delta = 0.4$  case is much too close to Biot Savart to give good agreement with the measured data. Thus, the correlation of the Betz theory with these rotary-wing measurements is not completely satisfactory. For a real test of the theory, simultaneous measurement of the bound circulation and the tip vortex properties is needed. This is not currently available for the rotary-wing case.

For the fixed-wing case, the measured data from Fig. 9 of [43] is presented in Fig. D.5. This data was taken using the same wing as [42]. Based on the span-loading from [42], an  $\eta_m = 0.7$  and a  $\delta = 0.3$  is chosen. Therefore

$$\gamma_b(x) = 0.7 + 0.3\sqrt{2x - x^2} \quad (D.30)$$

In this case,  $\alpha$  is known,  $\partial C_L / \partial \alpha = 4.0$  is assumed, and  $\Gamma$  is computed, using Eq. D.1. The resulting  $V_\theta$  for both the  $\gamma_b(x)$  of Eq. D.30 and for Biot Savart are plotted in Fig. D.5. There is reasonable agreement out to  $r/(b/2) = 0.15$ , where the measured data levels out. If the oscillations in the span-loading (near the wing tip) are not faired out, then  $\eta_m = 0.98$ . For this large  $\eta_m$ ,  $\rho_x(1.0)$  corresponds to  $r/(b/2) < 0.04$  for either the elliptical or the rectangular  $\gamma_b(x)$ . Since  $\gamma_b(x) = 1.0$  for all  $x > 1.0$ , this means that  $\eta_m = 0.98$  gives the Biot Savart value for  $V_\theta$  for all  $r/(b/2) > 0.04$ . Figure D.5 shows that this results in much worse agreement with the measured data when compared with the  $\eta_m = 0.7$  case (Betz Rectangular). Thus, the fairing seems to be justified.

In summary, the Betz model seems to work fairly well for the fixed-wing case, provided the oscillations are faired out. More experimental data (especially on span-loadings near the tip) is needed to verify the Betz model for rotary wings. The most practical result from the Betz model is the location of  $\eta_m$  at  $|d\Gamma_b/d\eta|_{\min.}$ , which is normally at the maximum  $\Gamma_b(\eta)$ . This gives a theoretical foundation for using the peak-bound circulation (instead of the average) as the total circulation of the rolled-up tip vortex.

## APPENDIX E

### AIRLOADS PROGRAM LDS-73

A listing of LDS-73 is provided in Appendix F. This appendix supplements that listing. An explanation of the order of the input data cards is provided. Most of the data is input by name lists. A set of lists defining all of the inputs in each name list is provided. Many of these input variables also appear in a COMMON statement and this is noted. A sample set of input data is given together with some notes on typical values for the inputs. A discussion of the output from LDS-73 is also provided. The output from a sample case is not provided, due to its great bulk.

LDS-73 is broken up into many subroutines. A short description of what each subroutine does is provided by comment cards in the listing in Appendix F. Most of the important variables in LDS-73 are transmitted between subroutines by various labeled COMMON statements. A set of lists defining all of the variables in each of the COMMON statements is provided. If a variable also appears in an input name list, this is noted. More detailed definitions of some of these variables appear in the List of Symbols.

#### E.1 LDS-73 Input Data

- 1) Read GENDAT (real) at start of each case
- 2) Read OPTCON (integer) at start of each case
- 3) If ( $ND > 0$  and  $ND \leq 3$ ) read distortion  $\hat{D}(\psi, \delta)$   
as punched out by WG-71  

```
DO K=1, NPHI
10 READ 20, ((D(I,J,K), I=1,3), J=1, NPSI)
20 FORMAT (6E13.6)
```
- 4) If ( $IPLX > 0$ )  
and ( $IRL \neq 2$ ) } Read experimental airloads  $XLDS(\eta, \psi)$   

```
DO 10 K=1, NE
10 READ 20, (XLDS(K,J), J=1, NPSI)
20 FORMAT (10F7.3)
```

5) If (IG=1) Read  $\alpha(\eta, \psi)$  from previous iteration plus  $\eta, \Delta\eta$

DO 10 K=1, NE

10 READ 20, (ALPHA(K,J), J=1,NPSI)

READ 30, (ETG(K), K=1,NE)

READ 30, (DETA(K), K=1,NE)

20 FORMAT (5E15.7)

30 FORMAT (10F6.3)

6) If (IRL $\neq$ 2) Read ROTOR

7) If (IRB<2) Read BEND

8) If (NG>IPRF) Read PERF

NAMELIST/PERF/IPRF, TH1, TC, TW

These inputs are defined under GENDAT(TH1), OPTCOU(IPRF), and ROTOR(TC, TW)

#### Sample Cases

A) Rigid wake (ND=0), start with  $\gamma_{bv}(\phi) = \gamma_o$  (IG=2), plot experimental airloads (IPLX=1):

GENDAT

OPTCOU

XLDS( $\eta, \psi$ ) cards

ROTOR

BEND

Note: Controls are set by program so that  $\vec{D}$ , XLDS, ALPHA, ROTOR, BEND are only read on the first iteration. When OPTCOU is read again at the start of a new case, these controls can be reset to read in these inputs again if desired.

B) Distorted tip vortex (ND=3), input  $\alpha(\eta, \psi)$  (IG=1), no XLDS (IPLX=0)

GENDAT

OPTCOU

$\vec{D}(\psi, \delta)$  cards

$\alpha(\eta, \psi)$  cards

$\eta$  card

$\Delta\eta$  card

ROTOR

BEND

Note: If it is desired to follow Case B with another case using the same  $\bar{D}$ , then when OPTCOU is read in again, make ND=4. This avoids reading in  $\bar{D}$  again and the program will reset ND=3 before execution. If a different  $\bar{D}$  is to be read in, leave ND=3.

C) In Case B, assume it is desired to try two different rotor blad designs (twist or thickness/chord). Then make IPRF<NI and read PERF after BEND.

## E.2 Name Lists

### E.2.1 NAMELIST/GENDAT/

EMU	$\mu$ (COMMON/SGAM) - Advance ratio ( $V/\Omega R$ )
AMBDA	$\lambda$ (COMMON/SQ LDS) - Uniform, average downwash perpendicular to TPP - used to determine rigid wake geometry. (nonD by tip speed)
EM	m - number of turns of wake included in the wake model - azimuthal extent of wake = $2\pi m$
RHOK	$\rho_k$ (COMMON/SQ LDS) - Nonburst value of $\rho_c$ - vortex core radius. (nonD by R)
DPS1	$\Delta\psi$ - Azimuth angle interval between positions of $\eta$ blade on which airloads are computed (degrees) - Note: DANG= $\Delta\psi$ (radians)
AO	$a_o$ (COMMON/BURST) - Coning angle (zeroth harmonic of rigid body flapping). This input value of $a_o$ is used only to compute $\hat{a}$ and $\hat{b}$ from $P_\eta$ to $P_a$ and $P_b$ . The value of $a_o$ computed in the blade motion portion of LDS-73 is a separate variable (radians).
BOER	$b/2R$ (COMMON/SGAM) - $b$ = rotor blade semichord (ft), $R$ = rotor radius (ft)
TANMU	$\mu \tan(i)$ (COMMON/SQ LDS) - Inflow (downwash) perpendicular to TPP due to flight speed (relative wind). (nonD by tip speed)
GZER	$\gamma_o$ (COMMON/SBVGS) - Constant value of bound circulation used for zeroth iteration (IG>1). (nonD by $2\pi b \Omega R$ )
EPSS	$\epsilon_s$ - Distance behind $\eta$ blade to start of near shed wake vortex sheet (when IEPS $\neq$ 2). (nonD by $b$ )

CTO  $C_T$  (COMMON/SLDS) - Input target value of thrust coefficient, iteration on collective pitch ( $\theta_o$ ) until  $C_T$  is achieved.

$$C_T = \frac{\text{Thrust}}{\rho \pi R^2 (\Omega R)^2}$$

SM  $\sigma$  (COMMON/SLDS) - Rotor solidity

$$\sigma = \frac{\text{rotor blade area}}{\text{rotor disk area}} = \frac{n_b C}{\pi R}$$

A  $a$  (COMMON/SGAM) -  $\partial C_2 / \partial \alpha$  - Input lift curve slope which is a constant. Various factors are used in blade motion and airloads computations to modify the effective  $\partial C_L / \partial \alpha$  (per radian).

TH1  $\theta_1$  (COMMON/SLDS) - Rotor blade linear twist (radians),  
 $\theta(\eta) = \theta_o + \theta_1 \eta$ .

RHOG  $\rho_g$  (COMMON/BURST) - Burst vortex core radius. (nonD by R).

WF  $w_f$  (COMMON/SGAM) - Weighting factor, to start a new iteration for circulation or blade motion take  $w_f$  times latest results plus  $(1 - w_f)$  times previous results.

VT  $V_T = \Omega R$  (COMMON/SLDS) - Rotor tip speed (ft/sec)

DEL (COMMON/PLT) - Interval size on airloads plots  
ordinate (lb/in)

ELMN(6) (COMMON/PLT) - Minimum value on airloads plot ordinate for each different  $\eta$  (lb/in)

QMO  $q_{mo}$  (COMMON/SQVLS) - Minimum value of the induced velocity contribution of any vortex line or vortex sheet segment for which a special printout is made in OSVL or OVS (nonD by tip speed).

ETG(6)  $\eta_k$  (COMMON/SGAM) - Radial stations on  $\eta$  blade of point P <sub>$\eta$</sub>  at which airloads are computed (nonD by R).

DELTA(6)  $\Delta \eta_k$  (COMMON/SGAM) - Delta  $\eta_k$  used in radial integrations (nonD by R).

EL(3)  $\ell_\ell$  (COMMON/SBVGS) - Radial stations on  $\ell$  blade of points  $P_\ell$  from which elements of vortex wake are shed.  
 $\ell_1$  = inboard edge of inboard trailing vortex sheet (ITVS)  
 $\ell_2$  = radial station of inboard trailing vortex line  
 $\ell_3$  = tip vortex (normally  $\ell_3 = 1.0$ ) (NonD by R)

DVB (COMMON/BURST) - If  $\Delta\ell_{xy} < \text{DVB}$  then delay tip vortex core bursting by  $[1 + 2(\text{DVB} - \Delta\ell_{xy})]$  (truncated to an integer)  $\Delta\phi$  intervals. This controls how much of any tip vortex line segment must have passed close to the  $\eta$  blade before the entire segment is burst.

FVB (COMMON/BURST) - If a tip vortex line segment passes within  $(\text{FVB})\rho_c$  above or below the  $\eta$  blade and the nearest end of the segment is between one segment length behind the  $\eta$  blade and one-half segment length ahead of the  $\eta$  blade ( $1.0 \leq \Delta\ell_{xy} \leq -1.5$ ) then a close blade-tip vortex interaction has occurred.

ELI(25)  $\ell_i(\phi)$  (COMMON/SQ LDS) - Radial station of outboard edge of inboard trailing vortex sheet at azimuth angle  $\phi$  (nonD by R)

ELT(25)  $\ell_t(\phi)$  (COMMON/SQ LDS) - Radial station of inboard edge of tip vortex sheet at azimuth angle  $\phi$  (nonD by R)

FTO(25)  $f_t^O(\phi)$  (COMMON/SQ LDS) - Fraction of total tip vortex circulation concentrated into tip vortex line at azimuth angle  $\phi$  and zero age ( $\delta=0$ )

FTD  $f_t^D$  (COMMON/SQ LDS) - Tip vortex rollup rate.  
 Fraction of total tip vortex circulation concentrated into tip vortex line =  $f_t(\phi, \delta)$   
 $f_t(\phi, \delta) = f_t^O(\phi) + (f_t^D)\delta$  until  $f_t(\phi, \delta)$  reaches 1.0  
 then  $f_t(\phi, \delta) = 1.0$ .

VSM (COMMON/SQ VLS) - Vortex sheet margin. If necessary the length ( $\Delta\ell$ ) of a vortex sheet segment is extended

so that the projection of  $P_\eta$  onto the vortex sheet is never closer than  $(VSM)\Delta\ell$  to either the front or back edges of the segment.

RMVS  $\rho_{vs}$  (COMMON/SQVLS) - Vortex sheet core radius (nonD by R)  
 DAM  $\Delta\alpha_m$  (COMMON/SQVLS) - Maximum change in local angle of attack due to any one vortex line or sheet segment (radians)

#### E.2.2 NAMELIST/OPTCOU

NB  $n_b$  (COMMON/SQLDS) - Number of rotor blades  
 NE  $n_\eta$  (COMMON/SGAM) - Number of radial stations  $\eta_k$  on  $\eta$  blade at which airloads are computed  
 NL  $n_\ell$  (COMMON/SQLDS) - Number of radial stations on  $\ell$  blade. For LDS-73, NL = 3.  
 NC Number of cases - When a case is finished NC is decreased by one and if NC is then greater than zero GENDAT and OPTCOU are read in and a new case is started.  
 NI (COMMON/SLDS) - Number of circulation iterations, when NG = NI this case is finished.  
 NG (COMMON/SGAM) - Current iteration number, increased by one after each iteration  
 IG (COMMON/SBVGs) - Indicates type of circulation computation used on first iteration.  
 IG=0: Compute bound circulation  $[\gamma_{bv}(\psi)]$  using angle of attack  $\alpha(\eta, \psi)$  from previous iteration stored in ALPHA(6,25)  
 IG=1: Compute  $\gamma_{bv}(\psi)$  using  $\alpha(\eta, \psi)$  read in from cards along with associated  $\eta_k$  and  $\Delta\eta_k$  which can be different from  $\eta_k$  and  $\Delta\eta_k$  in the rest of the program

IG>1: Zeroth iteration (NG=0), set all  $\gamma_{bv}(\psi) = \gamma_o =$   
 GZER (input GENDAT)  
 Note:  $\gamma_{bv}(\psi) = \text{constant}$  implies no shed wake; however,  
 $\gamma_s$  is made very small (but not zero) so that it will  
 make a negligible contribution to downwash, while the  
 influence coefficient matrix QMAT can still be com-  
 puted for use in later iterations.

ND (COMMON/SQLDS) - Value of subscript  $\ell$  for which a dis-  
 torted wake is used. If ND=NL=3: tip vortex  $\vec{D}(\phi, \delta)$  is  
 read in from cards punched by WG-71. If ND=0: Rigid  
 wake case, no  $\vec{D}(\phi, \delta)$  read in.

NH  $n_h$  (COMMON/SAMB) - Number of azimuthal harmonics in  
 harmonic analysis of downwash, airloads and blade  
 motion.

NQ When NG=NQ recompute influence coefficient matrix  
 QMAT.

IS (COMMON/SQLDS) - Shed wake indicator.  
 IS=2: Always neglect far shed wake if IEPS=2: neglect  
 near shed wake as well, if IEPS $\neq$ 2: include  
 vortex sheet representation of near shed wake.  
 IS $\neq$ 2: Include both near and far shed wake contributions.

IEPS (COMMON/SQLDS) - near shed wake indicator  
 IEPS=2: Concentrate near shed wake (wake within  $\Delta\phi$  of  
 $\eta$  blade) in a vortex line  $\Delta\phi$  behind  $\eta$  blade  
 IEPS $\neq$ 2: Spread near shed wake over a vortex sheet from  
 $\epsilon_s$  behind  $\eta$  blade to  $\Delta\phi$  behind  $\eta$  blade.

IVLAC (COMMON/BURST) - Controls use of lifting surface theory (LS)  
 and tip vortex core bursting (VCB) during close blade-tip  
 vortex interactions.

IVLAC	LS	VCB
2	no	yes
3	no	no
other	yes	yes

IABC (COMMON/SQ LDS) - Indicates wake model used.

IABC	Tip Vortex	Inboard Trailing Wake	Shed Wake
1	VL	none	VL
2	VL	VL	VL
4	VS + VL	VL	VL
5	VS + VL	VS	VL

VL = vortex line, VS = vortex sheet

IVCM (COMMON/BURST) - Indicates vortex core model used

IVCM=1: Fixed wing type vortex core model,

$$\gamma(\rho) = \rho^2 / (1 + \rho^2)$$

IVCM=2: Rotary wing vortex core model,

$$\gamma(\rho) = 0.2\rho^2 / (1 + \rho^2), \quad \rho \leq 1.0$$

$$\gamma(\rho) = 1.0 - 0.9e^{-0.075(\rho-1)}, \quad \rho \geq 1.0$$

$\rho$  = (radial distance from vortex line)/(vortex core radius)

IRL (COMMON/SLDS) - Controls reading of ROTOR in subroutine LOADS and reading of XLDS in MAIN, program sets IRL=2 at end of each iteration. If (IRL $\neq$ 2) read ROTOR, XLDS

IRB (COMMON/SLDS) - Controls reading of BEND in subroutine BLADE. If (IRB $\neq$ 2) read BEND.

IPRF (COMMON/SLDS) - Read PERF in subroutine LOADS when NG>IPRF.

IOQM Number of radial stations for which QMAT is printed starting at blade tip, if IOQM=0 no print of QMAT

IPGM If IPGM=0 suppress print of Glauert Mach number correction

IPL (COMMON/SLDS) - Controls printer plots of airloads by subroutine PLTL  
 If  $IPL = 1$  or  $NG \geq IPL$  call PLTL

IPLX (COMMON/PLT) - Controls reading, plotting, and harmonic analysis of experimental airloads (XLDS)  
 IPLX=0: No XLDS read in.  
 IPLX=2: Read, plot, and harmonic analyze XLDS

IUTQ Controls use of tangential component of induced velocity ( $UTQ$ ) in computation of tangential velocity ( $U_T$ ) at point  $P_\eta$ .  
 IUTQ=0:  $U_T = \eta + \mu \sin(\psi)$   
 IUTQ=1:  $U_T = \eta + \mu \sin(\psi) + UTQ$   
 IUTQ=2:  $U_T = \left\{ \begin{array}{l} \eta + \mu \sin(\psi) \\ \eta + \mu \sin(\psi) + UTQ \end{array} \right\} \quad \left( \begin{array}{l} \text{both cases} \\ \text{done} \end{array} \right)$

MEP (COMMON/SBVGS) - Value of  $k$  for smallest  $\eta_k$  considered when searching for radial peak circulation to determine bound circulation at each azimuth  $\phi$ .

NPOP (COMMON/SQ LDS) - Integer ratio  $(\Delta\phi/\Delta\psi)$ ,  $\Delta\phi = (NPOP)\Delta\psi$

NPRP (COMMON/SQ LDS) - Propagate tip vortex core bursting one additional  $\Delta\phi$  step for every NPRP  $\Delta\psi$  steps of blade motion since initial bursting.

NRNG (COMMON/SQ LDS) - Stop tip vortex core bursting when  $k_\phi = KPH1 = NPRP$  [ $\phi = (k_\phi - 1)\Delta\phi$ ].

NDLM (COMMON/SQ LDS) - Maximum azimuthal extent of input tip vortex distortion, measured in  $\Delta\psi$ , [ $(NDLM)\Delta\psi \leq 2\pi m$ ].

### E.2.3 NAMELIST/ROTOR

EPS  $\epsilon$  (COMMON/SLDS) - Rotor blade flapping hinge offset (nonD by R)

LN LN(COMMON/SLDS) - Rotor blade Locke Number (ratio aerodynamic forces/inertial forces)

$$LN = \frac{2\pi\rho c R^4}{I_b}, I_b = \text{rotor blade flapwise moment of inertia about flapping hinge (slug-ft}^2\text{)}$$

ALPS  $\alpha_s$  (COMMON/SLDS) - Stall angle of attack used in blade motion solution - dynamic stall used only in airloads computations given blade motion (input in degrees - used in radians).

CON (COMMON/SLDS) - Dimensionalizing constant for airloads:

$$CON = \frac{\rho c (\Omega R)^2 (1b/ft)}{2 (12 \text{ in/ft})} = (1b/in).$$

F F(COMMON/SLDS) - Theodorsen lift deficiency function used to approximate shed wake effects for zeroth iteration only.

EMT  $M_T$  (COMMON/SLDS) - Rotor tip Mach number.

TC(6)  $t_k$  (COMMON/SLDS) - Rotor blade thickness/chord ratio at radial stations  $\eta_k$ .

TW(6)  $\theta_k(\eta_k)$  (COMMON/SLDS) - Rotor blade twist at radial station  $\eta_k$  relative to  $\eta=0$  (radians)

$$\theta(\eta_k) = \theta_o + \theta_k(\eta_k)$$

IL Controls type of blade motion solution:  
HSL = harmonic solution, BLADE = numerical solution  
IL = 0: HSL with no second harmonics  
IL = 1: Both HSL and BLADE airloads  
IL = 2: HSL airloads only  
IL = 3: BLADE airloads only (note: HSL blade motion used as initial guess in BLADE)

IPRG Controls use of full or reduced airloads print  
(IPRG=0 or  $NG > IPRG$ ): full print; otherwise reduced print.

IPH Controls harmonic analysis of airloads.  
(IPH=1 or  $NG > IPH$ ): harmonic analysis

IPUN Controls punch of angle of attack  $\alpha(\eta, \psi)$ .  
 (IPUN=0 or  $\text{NG} > \text{IPUN}$ ): punch  $\alpha(\eta, \psi)$

#### E.2.4 NAMELIST/BEND

Define:  $R$  = rotor radius (ft)  
 $\epsilon$  = flapping hinge offset (nonD by  $R$ )  
 $L = (1 - \epsilon)R$  = length of blade outboard of hinge  
 $\bar{\epsilon} = \epsilon(R/L) = \frac{\epsilon}{1 - \epsilon}$   
 $\eta = r/R$  = radial coordinate (nonD by  $R$ )  
 $\bar{\eta} = \frac{\eta - \epsilon}{1 - \epsilon}$  radial coordinate from hinge to tip  
 $m(\bar{\eta})$  = radial blade mass distribution (slug/ft)  
 $\Omega$  = rotor angular velocity (radians/sec)  
 $a = \frac{\partial C_L}{\partial \alpha}$  = lift curve slope (per radian)  
 $c$  = blade chord (ft)  
 $\rho$  = air density (slug/ft<sup>3</sup>)  
 $I_b$  = blade flapwise moment of inertia about flapping hinge (slug-ft<sup>2</sup>)  
 $LN = \text{Locke Number } 2\pi\rho c R^4 / I_b$   
 $EI$  = flapwise stiffness (lb-ft<sup>2</sup>)

The mass integrals are given in two forms:

- a) the general form with  $m(\bar{\eta})$
- b) the special case  $m(\bar{\eta}) = m$  constant,  $I_b = \frac{mL^2}{3}$ ,

$$LN = \frac{2\pi\rho c R^4}{mL^3/3} = \frac{6\pi\rho c R}{m} \left(\frac{1}{1 - \epsilon}\right)^3$$

M1 
$$M_1 = \frac{2}{\rho a c R} \int_0^1 \bar{\eta} (\bar{\epsilon} + \bar{\eta}) m d\bar{\eta}$$

$$M_1 = \frac{2\pi}{LN a} \left(\frac{1}{1 - \epsilon}\right)^3 \left[ 2 + \left(\frac{3\epsilon}{1 - \epsilon}\right) \right]$$

M2

$$M_2 = \frac{2}{\rho a c R} \int_0^1 \bar{E} (4 \bar{\eta}^2 - 3 \bar{\eta}) m d\bar{\eta}$$

$$M_2 = \frac{-2\pi}{LN a} \left( \frac{1}{1-\varepsilon} \right)^3 \left( \frac{\varepsilon}{1-\varepsilon} \right)$$

M4

$$M_4 = \frac{2}{\rho a c R} \int_0^1 (\bar{E} + \bar{\eta}) \left( \frac{64}{3} \bar{\eta}^3 - 24 \bar{\eta}^2 + 9 \bar{\eta} \right) m d\bar{\eta}$$

$$M_4 = \frac{2\pi}{LN a} \left( \frac{1}{1-\varepsilon} \right)^3 \left[ \frac{38}{5} + 11 \left( \frac{\varepsilon}{1-\varepsilon} \right) \right]$$

M5

$$M_5 = \frac{2}{\rho a c R} \int_0^1 \bar{\eta}^2 m d\bar{\eta}$$

$$M_5 = \frac{4\pi}{LN a} \left( \frac{1}{1-\varepsilon} \right)^3$$

M6

$$M_6 = \frac{2}{\rho a c R} \int_0^1 (16 \bar{\eta}^4 - 24 \bar{\eta}^3 + 9 \bar{\eta}^2) m d\bar{\eta}$$

$$M_6 = \frac{3}{5} M_5$$

M7

$$M_7 = \frac{128 (1-\varepsilon)^4}{\rho a c R \Omega^2 R^4} \int_0^1 E I d\bar{\eta}$$

If  $\omega_2$  = natural frequency of 1st mode flapwise bending

$$M_7 = M_6 (\omega_2)^2 - M_4 - 9 K$$

K

$$K = \frac{2k}{\rho a c R \Omega^2 R^3} \left( \frac{1}{1-\varepsilon} \right)^3$$

Where  $k(\text{lb-ft})$  = spring constant of spring at flapping hinge used to simulate a cantilever rotor

NQIM

Maximum number of blade motion solution iterations in BLADE

MQCM

Maximum number of times  $\Delta\phi$  can be halved in BLADE when attempting to obtain convergence of blade motion

NTIM      Maximum number of iterations on collective pitch in BLADE  
when attempting to match required  $C_T = C_{TO}$

EQ          Maximum difference between amplitude of blade motion (or its  
slope) at  $\psi = 0$  and at  $\psi = 360^\circ$ . If the difference is greater  
than EQ not converged, therefore iterate.

ECT        Maximum difference between actual  $C_T$  and required  $C_T = C_{TO}$ .  
If difference > ECT not converged, therefore iterate.

### E.3 Sample Input Data for LDS-73

& GENDAT

EMU =  $\mu = 0.18$

AMBDA =  $\lambda = \mu \tan i + \frac{C_r}{2\sqrt{\lambda^2 + \mu^2}} = .0243$

EM =  $m = 2$  - ( $m \approx 0.4/\mu$  about right)

RHOK =  $\rho_k \approx .05 (c/R) = .0025$

DPSI =  $\Delta\psi = 15^\circ$

AO =  $a_o = .085$  radians - (estimate eqn. 3.3)

BOER =  $b/2R = .0122$

TANMU =  $\mu \tan i \approx \mu \left( \frac{f_g}{W} \right) = .009$  - (or eqn. 3.4)

GZER =  $\gamma_o = \frac{2 C_T / \sigma}{\pi (1 - \lambda_z^2)} = .067$

EPSS =  $\varepsilon_s = 0.5$  semi-chords - (Miller [9])

CTO =  $C_T = \frac{T}{\rho \pi R^2 (\Omega R)^2} = .0055$

$$SM = \sigma = \frac{n_b c}{\pi R} = .0622$$

$$A = a = \frac{dC_L}{d\alpha} = 5.73 \text{ per radian}$$

$$THI = \Theta_1 = -.14 \text{ radians } (-8^\circ)$$

$$RHOG = \rho_g = .10 \text{ - (typical)}$$

$$WF = W_f = 0.5$$

$$VT = V_T = \Omega R = 662 \text{ ft/sec}$$

$$DEL = 3.0$$

(plotting

$$ELMN(6) = -9, -9, -3, -3, -3, -3, \text{ parameters)}$$

$$QMO = q_{m_0} = .0020 \text{ - } (q_{m_0} \approx .1 \lambda \text{ gives reasonable print})$$

$$ETA(6) = \eta_k = .25, .40, .55, .75, .85, .95$$

$$DETA(6) = \Delta \eta_k = .225, .15, .225, .1, .1, .1$$

$$EL(3) = l_i = .10, .475, 1.0$$

$$DVB = 0.0001 \text{ - (do not make exactly 0.0)}$$

$$FVB = 20.0001$$

$$ELI(25) = .8, 3*.7, 8*.475, 6*.7, .8, .7, 5*.8$$

$$ELT(25) = 6*.9, 1.0, 1.0, 10*.9, 1.0, 1.0, 5*.9$$

$$FTO(25) = 5*.75, .5, 1.0, 1.0, .75, 9*.5, 1.0, 1.0, .75, .9, 3*.75$$

$$FTD = .050$$

$$VSM = 0.20$$

RMVS =  $\rho_{vs}$  = 0.0025 - (same as  $\rho_k$ )

DAM = 0.05 radians

Note: On choice of  $\eta$ ,  $\Delta\eta$ ,  $\ell$ : see Table for a good example of choice of

$\Delta\eta$ give $\eta$							
	$\ell_1$		$\ell_2$				$\ell_3$
$\ell_1 + \Delta\eta$	.1	.325	.475	.70	.80	.90	1.0
$\eta$	.25	.40	.55	.75	.85	.95	
$\Delta\eta$	.225	.15	.225	.10	.10	.10	

Start at  $\ell_1$  and end at  $\ell_3$ , try to center  $\eta$  between adjacent  $\ell_1 + \Delta\eta$ , take  $\ell_2$  as  $\ell_1 + \Delta\eta$  value near 0.5.

Note: ELI, ELT, FTO are based on circulation distribution from previous runs.

(typical good values)

IPRQ = 4 - print when NG = 4

IPRQ Controls print of components of airloads.

If (IPRQ = 0 or NG > IPRQ) print.

#### E.4 Input Variables Whose Values are Changed by the Execution of LDS-73

It if is desired to run several versions of the same basic case, with only minor variations, it is desirable to know which inputs must be reset because they have been changed by the execution of the basic case.

##### LDS-73

GENDAT - none (but GENDAT is always read)

OPTCOU - NG, IG, ND, IRL, IRB

NG = NI at end of a case

IG = 0 at end of each iteration

For distorted wake case, make ND = 3 On

first basic case thereafter make ND = 4

(reset ND = 3 by program) to avoid reading

D again.

IRL = IRB = 2 at end of each iteration. They

only need to be reset if it is necessary to

change something in ROTOR or BLADE

#### E.5 LDS-73 Outputs

##### E.5.1 Printed Output

The printed output is very extensive to provide a detailed picture of the source of the airloads and to aid debugging. For most cases, all of this

output is not needed and various indicators are included in the input data which can be used to suppress portions of the output. The output will be described here for the case where almost nothing is suppressed. It is presented in the order it would be printed out.

- 1) Label, Wake Model, CASE=IABC - output by MAIN
- 2) Input data from GENDAT and OPTCOU - output by PNTIN
- 3) If (IPGM.NE.0) Glauert Mach number correction for lift curve slope  $GMC(\eta, \psi)$  - output by MAIN
- 4) Iteration number - output by MAIN
- 5) If (IG.LE.1) Bound circulation data - output by GANT:  $ELB = \ell_2$ ,  
 $GBVR = \gamma(\eta, \psi)$   
 $GBVS$  not used,  $GBV(3) = \gamma_{bT}(\phi)$ ,  $GS(3) = \gamma_s(\phi)$   
 $GLMX(\psi) = \gamma(\eta_{NE}, \psi) / \gamma_{MAX}(\psi)$ ,  $GTMX$   
is  $GLMX$  extrapolated from  $\eta_{NE}$  to  $\eta = 1.0$
- 6) If (IG.LE.1) Print plot of  $\gamma_{bv}(\phi) / \gamma_o$  for both the last (\*) and next to last (+) iterations. If both iterations plot at the same point, only the (\*) is printed for that point.
- 7) Special print for any vortex line or sheet segment whose contribution to the induced velocity at point  $P_\eta$  (QL) is greater than QMD.

The vortex sheet print is one line and comes from QVS (far wake) or QLDS (near wake). The vortex line print is two lines long and comes from subroutine QSVL. There is another one line print from QLDS whenever vortex bursting first occurs. This can be distinguished from the vortex sheet line by the first symbols. The bursting line starts (IJK=) while the vortex sheet line starts (I=). The three different types of printout are mixed up randomly as they occur in the computation. For details on these printouts see the listings of the appropriate subroutines in Appendix F.

- 8) If (IOQM).GT.0) QMAT ( $\eta, \psi, \phi$ ) - output by MAIN
- 9) Tangential induced velocity component  $q_t(\eta, \psi)$  and tangential velocity  $U_T = \eta + \mu \sin\psi$  - output by MAIN
- 10) Downwash perpendicular to tip path plane TPP  

$$\lambda(\eta, \psi) = \mu \tan i + \sum_{\phi} \gamma_{bv}(\phi) * QMAT(\eta, \psi, \phi) - \text{output by MAIN}$$
- 11) Downwash contributions of individual blades ( $ZETA = \zeta$ ) and of tip vortex ( $\ell = 1.0$ ), inboard trailing wake ( $\ell = \ell_2$ ), and shed wake ( $\ell = \ell_1$ ), where  $EL = \ell$ .  

$$SUM(\eta, \psi, \zeta, \ell) = SUM(K, J, LB) \text{ where } K \text{ is } \eta \text{ subscript, } J \text{ is } \psi \text{ subscript, and } LB \text{ is a combined } \zeta, \ell \text{ subscript} - \text{output by MAIN}$$
- 12)  $\lambda(\eta, \psi) = \mu \tan i + \sum_{\ell} \sum_{\zeta} SUM(\eta, \psi, \zeta, \ell)$ , should be the same as item (10), and provides a check on QMAT - output by MAIN
- 13) Harmonic analysis of  $\lambda(\eta, \psi)$  - output by MAIN
- 14) Input data from ROTOR - output by LOADS
- 15) Harmonics of rigid body flapping and the contributions of thrust ( $C_T$ ), twist ( $\theta_1$ ), downwash harmonics ( $\lambda_o, \lambda_{2c}, \lambda_{1c}, \lambda_{2s}$ ), and second harmonic flapping ( $b_2, a_2$ ) to the harmonic blade motion solution. It is assumed:  $\beta(\psi) = a_o - a_1 \cos\psi - b_1 \sin\psi - a_2 \cos 2\psi - b_2 \sin 2\psi$ . The radial integrals of various  $\lambda$  harmonics times  $\eta$  or  $\frac{\eta - \epsilon}{1 - \epsilon}$  are also printed - output by HSL.
- 16) If (IL.LT.3) Airloads are computed using HSL blade motion data. These can be output here, the same way the blade bending airloads are output by PNTLDS, as described below.
- 17) Input data from BEND - output by BLADE
- 18) Harmonics of blade motion  $Q1 = q_1(\psi) = \beta(\psi)$   
 $Q2 = q_2(\psi) = \text{first mode blade bending, harmonic analysis}$   
is with + signs unlike  $\beta(\psi)$  in item (15) - output by BLADE

19) Blade motion  $Q1 = q_1(\psi)$ ,  $QD1 = dq_1/d\psi$ ,  $Q2 = q_2(\psi)$ ,  $QD2 = dq_2/d\psi$ , the  $\cos\psi$  and  $\sin\psi$  are just a check on the accuracy of these tables - output by BLADE

20) If (IPRQ.LE.O.OR.NG.GE.IPRQ) Components of airloads:  $LOADS = L^*(\eta, \psi)$ , where airloads (lb/in)

$$L(\eta, \psi) = \frac{\rho c V_T^2}{24} \frac{dC_L}{d\alpha} L^*(\eta, \psi), \quad \text{ALPHA} = \alpha(\eta, \psi),$$

$$\text{THETA} = \theta(\eta), \quad UP/UT = U_P(\eta, \psi)/U_T(\eta, \psi),$$

$$UT = U_T(\eta, \psi) = \text{tangential velocity at point } P_\eta,$$

$$UP = U_P(\eta, \psi) = \text{perpendicular velocity at point } P_\eta,$$

$$\text{LAMBDA} = \lambda(\eta, \psi), \quad \text{MU*Al} = \mu a_1 - \text{converts}$$

$$\lambda(\eta, \psi) \text{ from TPP to NFP, } Q1 = q_1(\psi) \mu \cos\psi,$$

$$Q2 = q_2(\psi) \left( \frac{d\gamma_2}{d\eta} \right) \mu \cos\psi, \quad QD1 = \eta \frac{dq_1}{d\psi},$$

$$QD2 = \gamma_2(\eta) \left( \frac{dq_2}{d\psi} \right) - \text{where } \gamma_2(\eta) = \text{first blade bending mode shape},$$

$$\text{DZDR} = \frac{dz(\eta, \psi)}{d\eta} \quad \text{where } z(\eta, \psi) \text{ is displacement of point } P_\eta \text{ perpendicular to TPP.}$$

Note:  $UP = \text{LAMBDA} + \text{MU*Al} + Q1 + Q2 + QD1 + QD2$ ,  $\text{ALPHA} = \text{THETA} - \tan^{-1}(UP/UT)$  - output by BLADE

21) Airloads (lb/in)  $L(\eta, \psi)$  and angle of attack (degrees)  $\alpha(\eta, \psi)$  - output by PNTLDS

22) If (IPRG.LE.O.OR.NG.GE.IPRG) Static stall angle of attack (degrees)  $\alpha_s(\eta, \psi)$  and reference angle of attack (degrees)  $\alpha_R(\eta, \psi)$  - which is used in dynamic stall model - output by PNTLDS

23) If (IPRG.LE.O.OR.NG.GE.IPRG) Thrust perpendicular TPP (lb), Azimuthal Force in TPP (lb), Radial Force in TPP (lb), Horizontal Force in TPP (lb) output by PNTLDS

- 24) If (IPRG.LE.O.OR.NG.GE.IPRG) Section drag coefficient  $C_D$ , CDM increment to  $C_D$  due to Mach number, blade element Mach number  $M(\eta, \psi)$ , drag divergence Mach number  $M_D(\eta, \psi)$  - output by PNTLDS
- 25) If (IPRG.LE.O.OR.NG.GE.IPRG) Airloads (lb/in)  
 $L(\eta, \psi)$  - same as in (21), airloads using old simple dynamic stall model - still used in blade motion computations, angle of attack if  $dC_L/d\alpha$  were not modified by dynamic stall, actual angle of attack - output by PNTLDS
- 26) If (IPRG.LE.O.OR.NG.GE.IPRG) Angle of attack  
 $\alpha(\eta, \psi)$  - same as in (21) and (25), Blade element contribution to  $C_T \times 10^6$  - output by PNTLDS
- 27) Blade element contribution to parasite torque coefficient  $C_{Q_P} \times 10^6$ ,  
blade element contribution to induced torque coefficient  $C_{Q_I} \times 10^6$  - output by PNTLDS
- 28)  $C_T$  (thrust),  $C_H$  (horizontal force),  $C_x$  (propulsive force),  $C_Q$  (torque),  $C_{Q_P}$  (parasite torque),  $C_{Q_I}$  (induced torque),  $L/D_E$  of aircraft,  
 $L/D_E$  of rotor alone,  $C_L^* = \frac{L}{qd^2\sigma}$ ,  $C_x^*$  from  $\frac{X}{qd^2\sigma}$  - output by LDS
- 29) If (IPH.EQ.1.OR.IPH.LE.NG) Harmonic analysis of airloads  $L(\eta, \psi)$  - output by HALDS
- 30) If (IPL.EQ.1.OR.IPL.LE.NG) Printer plots of airloads  $L(\eta, \psi)$  - output by PLTL
- 31) Iteration number and execution times - output by MAIN
- 32) Bound circulation - same as (5) except that GBVR is  $\gamma(\eta, \psi)$  from the most recent iteration while GBVS is  $\gamma(\eta, \psi)$  from the next most recent iteration. This allows a convergence check - output by GAMT
- 33) Same as item (6)
- 34) Same as items (9) and (10)
- 35) Same as items (13) through (30)

- 36) For each iteration repeat items (31) through (35)
- 37) On last iteration only - repeat items (1) and (2) and then output  
vortex bursting ages  $KPB(\psi)$  - output by MAIN
- 38) Same as items (31) through (33)

The  $SUM(\eta, \psi, \zeta, \ell)$  array cannot be computed from the  $QMAT(\eta, \psi, \phi)$  array because  $QMAT$  has already been summed over  $\ell$  and  $\zeta$  to save storage. Therefore, items (7), (11), and (12) cannot be repeated after the first iteration unless the induced velocity computation is repeated, which is very expensive.

To save printing costs, items (20), (22) through (26), (29), and (30) are normally suppressed for all but the last iteration. Item (16) is not normally used because airloads are not normally computed using HSL blade motion. The airloads plots (30) and items (37) and (38) are intended to be separated from the rest of the output to provide a summary of the output for one case. The bulky main output need only be referred to when extra detail is required.

In the event of an overflow, underflow, divide check, or square root of a negative argument, the extended error handling facility is used to call subroutine `FXSQRT`. This subroutine prints a large dump of every variable in every `COMMON` statement as an aid to debugging. The unformatted, namelist output is used. If the various iterations in subroutine `BLADE` do not converge within a specified number of tries, then some special output is printed by `BLADE`.

#### E.5.2 Punched Output

The only punched output is the angle-of-attack distribution  $\alpha(\eta, \psi)$ . This is normally the only output on the last iteration. It can be used to provide a basis for the computation of the bound circulation  $\gamma(\eta, \psi)$  in a WG-71 run or in a further LDS-73 run.

If (IPUN.EQ.O.OR.NG.GE.IPUN) Punch  $\alpha(\eta, \psi), \eta$

```

      DO 10 K = 1, NE
      PUNCH 20, ETG(K)
10    PUNCH 30, (ALPH(K,J), J=1, NPSI)
20    FORMAT (F6.3)
30    FORMAT (5E14.7)
```

The punched out  $\eta$  are only used to help visual identification of the  $\alpha(\eta, \psi)$ . The  $\eta$  cards must be removed before the  $\alpha(\eta, \psi)$  cards are input to either LDS-73 or WG-71.

## E.6 LDS-73 COMMON Statements

### E.6.1 COMMON/SQVLS/

Used in: MAIN, QLDS, QSVL, QVS, FXSQRT

- I Index  $i = \frac{n_b \zeta_i}{2\pi} + 1$ , ( $i = 1, n_b$ ), indicates which blade on an  $n_b$  bladed rotor is the  $i$  blade
- J Index  $j = \frac{\psi_j}{\Delta\psi} + 1$ , ( $j = 1, n_\psi$ ), indicates azimuth angle  $\psi_j$  of  $\eta$  blade
- K Index  $k$  for  $\eta_k$  ( $k = 1, n$ ), indicates radial station  $\eta_k$  at which induced velocity is computed
- KP Index  $k_\delta = \frac{\delta_{k_\delta}}{\Delta\psi} + 1$ , ( $k_\delta = 1, n_\delta$ ), indicates age  $\delta_{k_\delta}$  of wake element shed by  $i$  blade
- KPHI Index  $k_\phi = \frac{\phi_{k_\phi}}{\Delta\psi} + 1$ , ( $k_\phi = 1, n_\phi$ ) indicates azimuth angle  $\phi_{k_\phi}$  of  $i$  blade, although  $\phi_{k_\phi}$  goes up to  $2\pi m$  and  $\Delta\phi$  may be  $\neq \Delta\psi$ ,  $k_\phi$  is based on  $\Delta\psi$  and is cyclic (i.e., if  $\phi' = \phi'' + 2\pi$  then  $k'_\phi = k''_\phi$ )
- L Index  $\ell$  for  $\ell_\ell$  ( $\ell = 1, n_\ell$ ) indicates radial station on  $\ell$  blade from which wake element is shed
- IZ Indicates type of induced velocity computation in subroutines QVS and QSVL - see subroutine listings.
- XA, YA, ZA, XB, YB, ZB,  $x_a, y_a, z_a, x_b, y_b, z_b$  - The  $x, y, z$  components of  $\hat{a}$  and  $\hat{b}$  extending from point  $P_\eta$  on the  $\eta$  blade to endpoints  $P_a$  and  $P_b$  of the vortex line segment (or of the front edge of the vortex sheet segment), (nonD by R)
- ZM  $Z_m$  - In vortex sheet computations the mean  $z$  component of vectors from point  $P_\eta$  to the endpoints of the back edge of the vortex sheet (nonD by R)

VSM Vortex sheet margin (Input - GENDAT) - If necessary the length of a vortex sheet segment is extended so that the projection of point  $P_\eta$  onto the vortex sheet is never closer than VSM times the length ( $\Delta x$ ) of the sheet to either the front or back edges (those edges parallel to the circulation vector).

DELL  $\Delta \tilde{x}$  - Length of a vortex sheet segment perpendicular to its circulation vector (nonD by R)

GA  $\gamma_a \frac{b}{2R}$  - NonD (by  $2\pi b \Omega R$ ) circulation of vortex line (or vortex sheet) segment times rotor blade semichord over twice the rotor radius

QT  $\frac{q_t}{(\gamma_a b/2R)}$  - Tangential component of the induced velocity contribution of a vortex line (or sheet) segment at point  $P_\eta$  divided by GA times tip speed

QK  $\frac{q_k}{(\gamma_a b/2R)}$  - Downwash (k component of induced velocity) contribution of a vortex line (or sheet) segment at point  $P_\eta$  divided by GA times tip speed

RHVS  $\rho_{vs}$  (Input - GENDAT) Vortex sheet core radius (nonD by R)

DAM  $\Delta \alpha_m$  (Input - GENDAT) Maximum change in local angle of attack due to any one vortex line or vortex sheet segment (radians)

QMO  $q_{mo}$  (Input - GENDAT) - Minimum value of the induced velocity contribution of any vortex line or vortex sheet segment for which a special printout is made in QSVL or QVS (nonD by tip speed)

#### E.6.2 COMMON/BURST/

Used in: MAIN, PNTIN,QLDS,QSVL,FXSQRT

IVLAC (Input - OPTCOU) - Controls use of lifting surface theory (LS) and of vortex core bursting (VCB) during close blade-tip vortex interactions

IVLAC	LS	VCB
2	no	yes
3	no	no
other	yes	yes

IVCM (Input - OPTCOU) - Indicates vortex core model used.

IVCM=1: Fixed wing-type vortex core model,  $\gamma(\rho) = \rho^2/(1 + \rho^2)$

IVCM=2: Rotary wing-type vortex core model

$$\gamma(\rho) = \begin{cases} 0.2 \rho^2 / (1 + \rho^2) & , \rho \leq 1.0 \\ 1.0 - 0.9 e^{-.075(\rho-1)} & , \rho \geq 1.0 \end{cases}$$

DVB (Input - GENDAT) If  $\Delta l_{xy} < \text{DVB}$  then delay tip vortex core bursting by  $[1 + 2(\text{DVB} - \Delta l_{xy})]$  (truncated to an integer)  $\Delta\phi$  intervals. This controls how much of any tip vortex line segment must have passed close to the  $\eta$  blade before the entire segment is burst.

FVB (Input - GENDAT) If a tip vortex passes within  $(\text{FVB})\rho_c$  above or below the  $\eta$  blade and the nearest end of the vortex line segment is between one segment length behind  $\eta$  blade and one-half segment length ahead of  $\eta$  blade a close blade-tip vortex interaction has occurred. (Default values  $\text{DVB}=0.001$ ,  $\text{FVB}=2.001$ )

ETAC  $\eta_c$  - Radial location of the passage of a vortex line segment or its extension above or below  $\eta$  blade or its extension (nonD by R)

DLXY  $\Delta l_{xy}$  - Distance in TPP (Tip Path Plane) from nearest end of a vortex line segment to the  $\eta$  blade or its extension, measured parallel to the segment (nonD by segment length)

ZC  $Z_c$  - Z component of the distance from a vortex line segment or its extension to the  $\eta$  blade at the point of passage above or below the  $\eta$  blade (nonD by R)

RHOC  $\rho_c$  - Vortex core radius = radial distance from the center to the maximum induced velocity. Used in QSVL (nonD by R)

RHOG  $\rho_g$  (Input - GENDAT) Burst vortex core radius (nonD by R)

ABOER  $a (\frac{b}{2R})$  (Inputs - GENDAT)  $a = \frac{\partial C_L}{\partial \alpha}$  ,  
 $b$  = rotor blade semichord,  $R$  = rotor radius

ETA  $\eta$  - Radial station on  $\eta$  blade of point  $P_\eta$  at which induced velocity is computed (nonD by R)

AO  $a_o$  (Input GENDAT) - Coning angle (zeroth harmonic of rigid blade flapping). This input value of  $a_o$  is used only for determining  $\tilde{a}$  and  $\tilde{b}$  from  $P_\eta$  to  $P_a$  and  $P_b$ . The value of  $a_o$  computed in the blade motion portion of LDS-73 is a separate variable (radians)

HRS  $\rho^2 = (h/\rho_c)^2$ ,  $h$  = Radial distance from the center of the vortex line to point  $P_\eta$  (nonD by R) -  $\rho_c$  = vortex core radius (nonD by R)

GK  $\gamma(\rho)$  - Radial circulation distribution of a vortex line normalized so that  $\gamma(\infty) = 1.0$  and  $\gamma(1.0)$  gives the maximum induced velocity.

Fixed wing vortex core model:

$$\gamma(\rho) = \rho^2 / (1 + \rho^2)$$

Rotary wing vortex core model:

$$\gamma(\rho) = 0.2 \rho^2 / (1 + \rho^2) , \quad \rho \leq 1.0$$

$$\gamma(\rho) = 1.0 - 0.9 e^{-0.075(\rho-1)} , \quad \rho \geq 1.0$$

### E.6.3 COMMON/SINCO/

Used in: MAIN, GAMT, QLDS, QSVL, QVS, LOADS, BLADE, FXSQRT

S(97)  $\sin(\psi)$  tabulated every  $\Delta\psi$  from  $\psi = 0^\circ$  to  $\psi = 360^\circ$

C(97)  $\cos(\psi)$  tabulated every  $\Delta\psi$  from  $\psi = 0^\circ$  to  $\psi = 360^\circ$

UTS(6,25)  $U_T(\eta, \psi)$  = local tangential velocity parallel to blade chord  
 $U_T(\eta, \psi) = \eta + \mu \sin\psi + q_t(\eta, \psi)$  where  $q_t(\eta, \psi)$

is the tangential component of the induced velocity (nonD by tip speed)

#### E.6.4 COMMON/SGAM/

Used in: MAIN, PNTIN, GAMT, QLDS, LOADS, MSL, BLADE, HALDS, HART, PNTLDS, PLTL, FXSQRT

NE  $n_\eta$  (Input OPTCOU - number of radial stations  $\eta_k$  on  $\eta$  blade  
(NETA in: LOADS, HSL, BLADE, HALDS, PNTLDS)

NPS1  $n_\psi = \frac{2\pi}{\Delta\psi} + 1$  - Number of azimuth angles  $\psi$  considered. (NPS10 in BLADE)

NPS NPS1-1 (NPS0 in BLADE)

NG (Input OPTCOU) - Current iteration number, increased by one after each iteration

WF  $w_f$  (Input GENDAT) - Weighting factor, to start a new iteration for circulation or blade motion, take  $w_f$  times latest results plus  $(1 - w_f)$  times previous results

EMU  $\mu$  (Input GENDAT) - Advance ratio ( $V/R$ )

A  $a$  (Input GENDAT) -  $\frac{\partial C_L}{\partial \alpha}$ . This input value remains constant during execution and various factors are used in blade motion and airloads computations to modify the effective  $\frac{\partial C_L}{\partial \alpha}$  (per radian)

BOER  $\frac{b}{2R}$  (Input GENDAT) -  $b$  = rotor blade semichord,  $R$  = rotor radius

DANG  $\Delta\psi$  - Azimuth angle interval size (radians), (DANGO in BLADE)

SUM(6, 25, 18)  $q_z(\eta, \psi, \zeta, \ell)$  -  $z$  component of the contribution to the induced velocity at point  $P_\eta$  of the wake from radial station  $\ell$  on the  $\zeta$  blade. There is provision for 6 $\eta$ , 25 $\psi$ , and 18 $\zeta$ ,  $\ell$  combinations (6 $\zeta$  and 3 $\ell$ ) (nonD by tip speed)

Note: After SUM( $\eta, \psi, \zeta, \ell$ ) is printed out, other arrays are stored in the same space by means of EQUIVALENCE statements

ETG(6)  $\eta_k$  (Input GENDAT) - Radial stations on  $\eta$  blade of point P <sub>$\eta$</sub>  at which airloads are computed (nonD by R), (ETP(6) in: GAMT, BLADE)

DETA(6)  $\Delta\eta_k$  (Input GENDAT) - Delta  $\eta_k$  used in radial integrations (nonD by R), (DETP(6) in GAMT)

ANG(25)  $\psi_j$  - Azimuth angles of  $\eta$  blade measured in degrees, used only for output (U(25) in PLTL)

PSI(25)  $\psi_j$  - Azimuth angles of  $\eta$  blade measured in radians, used for computations.

ALPHA(6,25)  $\alpha(\eta,\psi)$  - Angle-of-attack distribution as a function of radius ( $\eta$ ) and azimuth ( $\psi$ ) used for computation of circulation distribution, can be input or obtained from a previous iteration. (ALPH(6,25) in: LOADS,HSL,BLADE,HALDS,PNTLDS)

#### E.6.5 COMMON/SBVGS/

Used in: MAIN, PNTIN,GAMT,QLDS,FXSQRT

IG (Input OPTCOU) - Indicates type of circulation computation used.

IG Circulation [ $\gamma_{bv}(\psi)$ ] computation used

0 Compute  $\gamma_{bv}$  using  $\alpha(\eta,\psi)$  from previous iteration stored in ALPHA(6,25)

1 Compute  $\gamma_{bv}$  using  $\gamma(\eta,\psi)$  read in from cards along with associated  $\eta_k$  and  $\Delta\eta_k$  which can be different from  $\eta_k$  and  $\Delta\eta_k$  in the remainder of the program

2 Zeroth iteration, set all  $\gamma_{bv}(\psi) = \gamma_o$  (GZER - Input GENDAT) for all  $\psi$ , therefore  $\gamma_s$  should be zero, instead make  $\gamma_s$  small but finite so that it will not contribute to  $\lambda(\eta,\psi)$  but its influence coefficient will be computed.

MEP (Input OPTCOU) - Value of k for smallest  $\eta_k$  considered when searching for radial peak circulation to determine bound circulation at each azimuth  $\phi$ .

GZER  $\gamma_o$  (Input GENDAT) - Constant value of bound circulation used in zeroth iteration (IG>1) (nonD by  $2\pi b\Omega R$ )

- FL(3)  $\ell_\ell$  (Input GENDAT) - Radial stations on  $\ell$  blade of points  $P_\ell$  from which elements of vortex wake are shed.  $\ell_1$  = inboard edge of inboard trailing vortex sheet,  $\ell_2$  = outboard edge of inboard trailing sheet or location of inboard trailing vortex line,  $\ell_3$  = location of tip vortex (normally  $\ell_3 = 1.0$ ) (nonD by R)
- BV(25)  $\frac{b}{2R} \gamma_{bv}(\psi_j)$  - Bound circulation as a function of azimuth times  $(\frac{b}{2R})$  (nonD by  $2\pi b\Omega R$ )
- GS(25)  $\frac{b}{2R} \gamma_s(\psi_j)$  - Shed circulation as a function of azimuth times  $(\frac{b}{2R})$  (nonD by  $2\pi b\Omega R$ )

#### E.6.6 COMMON/SQLDS/

Used in MAIN, PNTIN, QLDS, FXSQRT

IABC (Input OPTCOU) - Indicates wake model used.

IABC	Tip Vortex	Inboard Trailing Wake	Shed Wake
1	VL	none	VL
2	VL	VL	VL
4	VL+VS	VL	VL
5	VL+VS	VS	VL

IEPS (Input OPTCOU) - If IEPS $\neq$ 2: Spread near shed wake (from  $\Delta\phi$  nearest the  $\eta$  blade) over a vortex sheet starting  $\epsilon_s$  behind the blade. If IEPS=2: concentrate near shed wake (from  $\Delta\phi$  nearest the  $\eta$  blade) in a vortex line  $\Delta\phi$  behind the  $\eta$  blade.

IS (Input OPTCOU) - If IS $\neq$ 2: Compute both near and far shed wake contributions to induced velocity.  
If IS=2: Neglect far shed wake always, and if IEPS=2, neglect near shed wake as well, if IEPS $\neq$ 2 include the vortex sheet representation of the near shed wake.

KZAD  $(\frac{2\pi}{n_b \Delta\psi})$  - Increment in  $\zeta_i$  for each unit increment in  $i$

NB  $n_b$  (Input OPTCOU) - Number of rotor blades

NL  $n_\ell$  (Input OPTCOU) - Number of radial stations  $\ell_\ell$  on  $\ell$  blade.  
For LDS-73,  $n_\ell = 3$

ND (Input OPTCOU) - Value of  $\ell$  for which a distorted wake is used,  
 $\vec{D}(\phi, \delta)$  is read in from cards output by WG-71,  
If ND=0: Rigid wake case, no  $\vec{D}(\phi, \delta)$  read in.

NDEL  $n_\delta = (\frac{2\pi m}{\Delta\psi} + 1)$  - Maximum azimuth extent of wake,  
measured in  $\Delta\psi$ .

NPOP (Input OPTCOU) - Integer ratio  $\Delta\phi/\Delta\psi$

NPRP (Input OPTCOU) - Propagate tip vortex core bursting one  
additional  $\Delta\phi$  step for every NPRP  $\Delta\psi$  steps of blade motion  
since initial bursting.

NRNG (Input OPTCOU) - Stop tip vortex core bursting propagation  
at KPH1=NRNG

NDLM (Input OPTCOU) - Maximum azimuthal extent of input tip vortex  
distortion, measured in  $\Delta\psi$ , (NDLM  $\leq$  NDEL)

FTD  $f_t^D$  (Input GENDAT) - Tip vortex rollup rate, tip vortex line  
circulation as a fraction of total tip vortex circulation  
 $f_t(\phi, \delta)$  is increased by  $\Delta\phi * f_t^D$  every  $\Delta\phi$  step in age until all  
tip vortex circulation is concentrated in the vortex line  
( $f_t(\phi, \delta) = 1.0$ )

RHOK  $\rho_k$  (Input GENDAT) - Nonburst value of  $\rho_c$  - vortex core radius  
(nonD by R)

DPHR  $\Delta\phi$  - Azimuth angle increment between successive positions of  $\ell$   
blade (azimuthal extent of trailing vortex line segment) (radians)

TANMU  $\mu_{tan}(i)$  (Input GENDAT) - Inflow (downwash) perpendicular to  
TPP due to flight speed (relative wind) (nonD by tip speed)

AMBDA  $\lambda$ (Input GENDAT) - Uniform, average downwash perpendicular to TPP - used to determine rigid wake geometry (nonD by tip speed)

ZETA(6)  $\zeta_i$  - Azimuth angle difference between ith  $\ell$  blade and  $\eta$  blade.  
For  $n_b$  bladed rotor:  $\zeta_i = (i - 1) \frac{2\pi}{n_b}$

KPB(25)  $k_{\delta}^b(\phi)$  - Tip vortex core bursting occurs at azimuth  $\phi$  when point  $P_{\ell}$  reaches age  $\delta > \Delta\psi[k_{\delta}^b(\phi)]$ ,  $k_{\delta}^b(\phi) = 1 + (\delta_b(\phi) / (\Delta\psi))$

ELT(25)  $\ell_t(\phi)$  (Input GENDAT) - Radial station of inboard edge of tip vortex sheet at azimuth angle  $\phi$  (nonD by R)

ELI(25)  $\ell_i(\phi)$  (Input GENDAT) - Radial station of outboard edge of inboard trailing vortex sheet at azimuth angle  $\phi$  (nonD by R)

FTO(25)  $f_t^o(\phi)$  (Input GENDAT) - Fraction of total tip vortex circulation concentrated into tip vortex line at azimuth angle  $\phi$  and zero age ( $\delta = 0$ )

#### E.6.7 COMMON/SAMB/

Used in: MAIN, LOADS, HSL, BLADE, HALDS, HART, FXSQRT

NH  $n_h$  (Input OPTCOU) - Number of azimuthal harmonics in harmonic analysis of downwash airloads and blade motion

AMB(25, 6)  $\lambda(\psi, \eta)$  - Computed downwash perpendicular to TPP at point  $P_{\eta}$  - at azimuth  $\psi$  and radial station  $\eta$  (nonD by tip speed),  
(AMBDA(25,6) in: LOADS, HSL, BLADE, HALDS)

AMBO(6)  $\lambda_o(\eta)$  - Zeroth azimuthal harmonic of  $\lambda(\psi, \eta)$

CLAM(9, 6)  $\lambda_{nc}(\eta)$  - nth cosine azimuthal harmonic of  $\lambda(\psi, \eta)$

SLAM(9, 6)  $\lambda_{ns}(\eta)$  - nth sine azimuthal harmonic of  $\lambda(\psi, \eta)$

#### E.6.8 COMMON/SLDS/

Used in: MAIN, PNTIN, LOADS, HSL, BLADE, PLTL, FXSQRT

- IRB (Input OPTCOU) - Controls reading of namelist BEND in subroutine BLADE. If IRB<2: read BEND, otherwise do not.
- IRL (Input OPTCOU) - Controls reading of namelist ROTOR in subroutine LOADS. If IRL≠2: read ROTOR. If IRL=2: do not read ROTOR
- IPL (Input OPTCOU) - Controls printer plots of airloads by subroutine PLTL. If IPL=1 or IPL<NG (iteration number): call PLTL, otherwise do not.
- IPRF (Input OPTCOU) - Controls reading of namelist PERF in subroutine LOADS. If IPRF<NG (iteration number): read PERF. Otherwise do not.
- IUT Controls operations in subroutine LOADS when IUTQ=2; i.e., airloads are computed both with (IUT=9) and without (IUT=2) tangential induced velocity. If IUT=2: suppress punch out  $\alpha(\eta, \psi)$ , harmonic analysis of airloads and plots of airloads. If IUT=9: suppress reading of namelist ROTOR, printing airloads inputs and harmonic blade motion solution.
- NI (Input OPTCOU) - Number of circulation iterations to be run. When NG=NI, stop.
- CTO  $C_T$  (Input GENDAT) - Input target value of thrust coefficient, iteration on collective pitch ( $\theta_o$ ) until  $C_T$  is achieved.
- $$C_T = \frac{\text{thrust (lb)}}{\rho \pi R^2 (\Omega R)^2}, \quad \rho = \text{air density (slug/ft}^3\text{)}, \quad R = \text{rotor radius (ft)},$$
- $$\Omega R = \text{tip speed (ft/sec)}$$
- SM  $\sigma$  (Input GENDAT) - Rotor solidity:
- $$\sigma = \frac{\text{rotor blade area}}{\text{rotor disk area}} = \frac{c n_b}{\pi R}$$
- $$c = \text{rotor blade chord (ft)}$$
- TH1  $\theta_1$  (Input GENDAT) - Rotor blade linear twist (radians),
- $$\theta(\eta) = \theta_o + \theta_1 \eta$$

VT	$V_T = \Omega R$ (Input GENDAT) - Rotor tip speed (ft/sec)
EPS	$\epsilon$ (Input ROTOR) - Rotor blade flapping hinge offset (nonD by R)
LN	LN (Input ROTOR) - Rotor blade Locke number (ratio aerodynamic forces/inertia forces) $LN = (2\pi\rho c R^4)/I_b$ . $I_b$ = rotor blade flapwise moment of inertia about flapping hinge (slug-ft <sup>2</sup> ).
F	F(Input ROTOR) - Theodorsen lift deficiency function used to approximate shed wake effects only for zeroth iteration or when IS=2 (no shed wake used)
CON	(Input ROTOR) - Constant used to obtain dimensional airloads: $CON = \frac{\rho c (\Omega R)^2 (lb/ft)}{2(12 \text{ in/ft})}$
ALPS	$\alpha_s$ (Input ROTOR) - Stall angle of attack, read in as degrees used in radians
COSI	Cosine of angle i between relative wind and TPP
GMA	Average Glauert Mach number correction to $\frac{\partial C_L}{\partial \alpha} : \frac{\partial C_L}{\partial \alpha} = \frac{a}{GMA}$ , $GMA = 1 - (.75M_T)^2$ , $M_T$ = rotor tip Mach number
ELO	$EL(1)=\ell_1$ - Inboardmost radial station $\ell$ - normally radius of rotor blade root cutout (nonD by R)
OMEPS	$1-EPS=1-\epsilon$ - Length of rotor blade outboard of flapping hinge (nonD by R)
EMT	$M_T$ (Input ROTOR) - Rotor tip Mach number $(\frac{\text{tip speed}}{\text{speed of sound}})$
EMS	$EMU*EMU=\mu^2$ - Advance ratio squared
DENTH	Denominator of expression for collective pitch ( $\theta_o$ ) - a very complicated function of $\mu$ , $\epsilon$ , and $\ell_1$

ALMU  $\text{EMU} \cdot A_1 = \mu a_1 = (\lambda_{\text{NFP}} - \lambda_{\text{TPP}})$  - Inflow through NFP due to 1st harmonic flapping  
 AZERO  $a_0$  - Zeroth harmonic of rigid blade flapping motion (coning angle).  
 Computed value from blade motion solution not to be confused with AO which is input (radians)  
 AONE,  $a_1, b_1$  - Harmonics of rigid blade flapping motion -  
 BONE,  $a_2, b_2$   $\beta(\psi) = a_0 - a_1 \cos\psi - b_1 \sin\psi - a_2 \cos 2\psi - b_2 \sin 2\psi$  (radians)  
 ATWO,  
 BTWO  
 THETAO  $\theta_0$  - Collective pitch at zero radius (radians)  
 ETE(6)  $\eta_k = \frac{\eta_k - \epsilon}{1 - \epsilon}$  - Radial stations on blade measured from flapping hinge instead of center of rotation (nonD by  $L = (1 - \epsilon)R$ ),  
 (ETA(6) in: LOADS, HSL, BLADE)  
 TC(6)  $t_k$  (Input ROTOR) - Rotor blade thickness/chord ratio at radial stations  $\eta_k$  on  $\eta$  blade  
 ELDS(6)  $\Sigma L(\eta, \psi)$  - Sum over azimuth of airloads at radial station  $\eta$  -  
 $\psi$   
 used to find zeroth harmonic of airloads  
 TW(6)  $\theta_k(\eta_k)$  (Input ROTOR) - Rotor blade twist at radial station  $\eta_k$  relative to  $\eta = 0$  (radians)

$$\theta(\eta_k) = \theta_0 + \theta_k(\eta_k)$$

GMC(6, 25)  $G_M(\eta, \psi)$  - Glauert Mach number correction:

$$\frac{dC_L}{d\alpha} = a/G_M(\eta, \psi)$$

$$G_M(\eta, \psi) = \text{Max.} \left\{ \begin{array}{l} \sqrt{1 - (\eta + \mu \sin\psi)^2 M_T^2} \\ 0.60 \end{array} \right.$$

#### E.6.9 COMMON/PLT/

Used in: MAIN, HALDS, PLTL

IPLX (Input OPTCOU) - Controls reading in plotting and harmonic analysis of experimental airloads.

0 no experimental airloads  
IPLX 1 read in and plot exp. airloads  
2 read in, plot and harmonic analyze experimental airloads

DEL (Input GENDAT) - Interval size on airloads plots ordinate (lb/in)

ELMN(6) (Input GENDAT) - Minimum value on airloads plot ordinate for each different  $\eta$  (lb/in)

XLDS(6, 25) (Read in if IPLX $\neq$ 0) - Experimental airloads at radial station  $\eta$  and azimuth angle  $\psi$  for  $6\eta$  and  $25\psi$  (lb/in)

#### E.6.10 COMMON/SFX/

Used in: MAIN, QLDS, FXSQRT

PZAP  $\delta = \psi + \zeta - \phi$ , Age of point  $P_\eta$

GPS  $\frac{\epsilon_s b}{R}$  - Distance behind  $\eta$  blade to start of near shed wake vortex (nonD by R)

QTAN(6, 25, 25)  $\frac{q_t(\eta, \psi, \phi)}{\gamma_{bv}(\phi)}$  - Influence coefficient matrix which when multiplied by bound circulation  $\gamma_{bv}(\phi)$  at azimuth angle  $\phi$  gives tangential induced velocity at point  $P_\eta$  (radial station  $\eta$  and azimuth angle  $\psi$ ) due to all wake elements involving bound circulation  $\gamma_{bv}(\phi)$ ; i.e., all trailing wake elements having azimuth angle  $\phi$  plus shed wake elements having azimuth angles  $\phi$  and  $\phi - \Delta\phi$  (nonD by tip speed)

VI(3), VK(3),  $\hat{i}, \hat{j}, \hat{k}$  (x,y,z) components of  $\hat{a}$  and  $\hat{b}$  from point  $P_\eta$  on  $\eta$  blade to points  $P_a$  and  $P_b$  in wake as a function of  $\ell$  - radial station on  $\ell$  blade at azimuth angle  $\phi$  (nonD by R)

OVI(3),OVJ(3), Same as above but for  $\phi - \Delta\phi$   
 OVK(3)

D(3,25,97)  $\vec{D}(\phi, \delta)$  - x,y,z components of distortion vector at point  
 $P_\ell$  (radial station  $\ell_{ND}$ , azimuth angle  $\phi$ , and age  $\delta$ ) (nonD  
 by R)

QMAT(6,25,25)  $\frac{q_z(\eta, \psi, \phi)}{\gamma_{bv}(\phi)}$  - Influence coefficient similar to QTAN but  
 for z component of induced velocity (nonD by tip speed)

#### E.6.11 COMMON/SVS/

Used in: QVS, SFX

DX,DY,DZ  $\Delta x, \Delta y, \Delta z - \Delta x = x_b - x_a, \Delta y = y_b - y_a, \Delta z = z_b - z_a$

DXYS  $\Delta x^2 + \Delta y^2$

CL,CLS  $|\vec{c}|, |\vec{c}|^2 - \vec{c} = \vec{b} - \vec{a}, |\vec{c}|^2 = \Delta x^2 + \Delta y^2 + \Delta z^2$

CA,CB  $C_a, C_b$

ZI  $z_x$   
 RAD  $\sqrt{(\Delta x^2 + \Delta y^2) - z_x^2} |\vec{c}|^2$

ZID  $z_x \Delta z$

XI,YI  $x_x, y_x$

XK,YK,ZK  $x_z, y_z, z_z$

CAN  $C_a / |\vec{c}|$

XH,YH,ZH  $x_h, y_h, z_h$

X1  $x_1$

Z,ZZ  $z_1, z_1^2$

X2,Z2S  $x_2, x_2^2$

X1S  $x_1^2$

CAS,CBS	$c_a^2, c_b^2$
SOA	$s_{1a} = \sqrt{x_1^2 + z_1^2 + c_a^2}$
SOB	$s_{1b} = \sqrt{x_1^2 + z_1^2 + c_b^2}$
STA	$s_{2a} = \sqrt{x_2^2 + z_1^2 + c_a^2}$
STB	$s_{2b} = \sqrt{x_2^2 + z_1^2 + c_b^2}$
I1	$I_1$
I2	$I_2$

## APPENDIX F

### LISTING OF LDS-73

This program is normally compiled and executed on an IBM 370/168 running under release 21.7 of OS/MVT (Operating System/Multiprogramming with a variable number of tasks) with release 21.6 of FORTRAN G1. The core storage requirement is 180k. The subroutine ERASE, which is used, but not listed, is an MIT library routine which sets all elements of an array to zero.

## APPENDIX G

### BLADE BENDING MODE SHAPE

The blade bending mode shape is chosen to be the simplest function which will satisfy the most important boundary conditions. The minimum power series polynomial for this purpose is a quadratic. For comparison, a quartic is also considered. The mode shape is a function of the radial mass distribution  $m(\bar{\eta})$  of the blade. Normally, this is assumed to be uniform outboard of the flapping hinge. The case of a concentrated tip mass on an otherwise uniform blade will also be considered.

For the quadratic case, it is assumed that  $m(\bar{\eta})$  is a constant,  $m$  (slug/ft). The assumed mode shape is:

$$Y_2(\bar{\eta}) = a \bar{\eta}^2 + b \bar{\eta} + c \quad (G.1)$$

The boundary conditions are:

- 1) Zero displacement at the flapping hinge:

$$Y_2(0) = 0.0 \quad (G.2)$$

- 2) Unit displacement at the blade tip:

$$Y_2(1.0) = 1.0 \quad (G.3)$$

- 3) Orthogonality with the rigid body mode:

$$\int_0^1 \bar{\eta} Y_2(\bar{\eta}) d\bar{\eta} = 0.0 \quad (G.4)$$

These conditions lead to:

$$\gamma_2(\bar{\eta}) = 4\bar{\eta}^2 - 3\bar{\eta} \quad (\text{G.5})$$

For the quartic case  $m(\bar{\eta})$  is again assumed to be a constant  $m$  (slug/ft). The assumed mode shape is:

$$\gamma_2(\bar{\eta}) = a\bar{\eta}^4 + b\bar{\eta}^3 + c\bar{\eta}^2 + d\bar{\eta} + e \quad (\text{G.6})$$

Two extra boundary conditions can be included compared to the quadratic case:

- 4) Zero bending moment at the flapping hinge:

$$\left( \frac{d^2 \gamma_2}{d\bar{\eta}^2} \right)_{\bar{\eta}=0} = 0.0 \quad (\text{G.7})$$

- 5) Zero bending moment at the blade tip:

$$\left( \frac{d^2 \gamma_2}{d\bar{\eta}^2} \right)_{\bar{\eta}=1.0} = 0.0 \quad (\text{G.8})$$

The result is:

$$\gamma_2(\bar{\eta}) = \frac{-\bar{\eta}}{3} (10\bar{\eta}^3 - 20\bar{\eta}^2 + 7) \quad (\text{G.9})$$

The  $\gamma_2(\bar{\eta})$  shapes obtained from Eq. G.5 and Eq. G.9 are compared in Fig. G.1. There is very little difference, so the simpler quadratic expression (Eq. G.5) is normally used.

Finally, consider the case of a concentrated tip mass of  $M$ (slugs) on an otherwise uniform blade. The length and running mass of the blade outboard of the flapping hinge are  $L$ (ft) and  $m$  (slug/ft), respectively. Using a quartic  $\gamma_2(\bar{\eta})$  and the same

five boundary conditions:

$$Y_2(\bar{\eta}) = 10\bar{\eta} \left[ \left( \frac{M}{mL} \right) - \frac{1}{3} \right] \left[ \bar{\eta}^3 - 2\bar{\eta}^2 + \frac{30 \left( \frac{M}{mL} \right) - 7}{30 \left( \frac{M}{mL} \right) - 10} \right] \quad (G.10)$$

## APPENDIX H

### WAKE GEOMETRY PROGRAM WG-71

A listing of WG-71 is given in Appendix I. This appendix supplements that listing. The order of the input data is explained. Most of the data is input by NAMELIST. A set of lists defining the inputs in each NAMELIST is therefore given. If an input variable also appears in a COMMON statement this is noted. An annotated set of sample input data for WG-71 is given. The output is not included, due to its great bulk. Finally, there is an alphabetical list which defines the most important variables.

#### H.1 WG-71 Input Data

- 1) Read WDAT (real) at start of each case.
- 2) Read WCON (integer) at start of each case.
- 3) If (IG=1) Read ADETA  
    Read  $\alpha(\eta, \psi)$  from LDS-73.  
    DO 10 K=1, NE  
    10 READ 20, (ALPHA(K, J), J=1, NPSI)  
    20 FORMAT (5E14.7)
- 4) If (I1 > 0) Read distortion  $\hat{D}(\psi, \delta)$  as punched out by a previous WG-71 run.  
    DO 10 K=1, NPPMI  
    10 READ 20, ((D(I, J, K), I=1, 3), J=1, NPSI)  
    20 FORMAT (6E13.6)
- 5) If (CALCOMP Plot) Read DPLT  
    ILAB      If ILAB=2 no label on plot  
    SR      TPP scale factor, rotor radius is SR inches in plot  
    SK      Vertical scale factor, can be different from SR, if  
            expanded vertical scale is desired
- 6) If (CALCOMP Plot and ILAB $\neq$ 0)  
    then: Read plot labels (2 cards)  
        Labels are the image of columns 1-60
- 7) If (CALCOMP Plot) Read  $\psi_s$  and number of  $\psi_s$   
    READ 10, J1, NS  
    10 FORMAT (I3, I2)

$J1 = 1 + (\psi_s / \Delta\psi)$  where  $\psi_s$  = starting azimuth of plotted wake =  
position of the  $\eta$  blade which shed plotted wake  
NS = number of different  $\psi_s$  cases plotted; last (J1, NS) card has  
NS=1

Program expects a set of plot input cards [5, 6, 7 above] for every iteration of  $\vec{D}$  plotted.

## H.2 Namelists

### H.2.1 NAMELIST/WDAT/

EMU  $\mu$ (COMMON/SSPLOT) - Advance ratio (normalized by tip speed)  
AMBDA  $\lambda$ (COMMON/SSPLOT) - Uniform, average downwash perpendicular to TPP - used to determine rigid wake geometry (normalized by tip speed)  
TANMU  $\mu_{tani}$ (COMMON/SQCAL) - Inflow (downwash) perpendicular to TPP due to flight speed (relative wind) (normalized by tip speed)  
ETA  $\eta$ (COMMON/SSPLOT) - Radial station of point  $P_\eta$ , at which the distortion is computed normally  $\eta = 1.0$  for tip vortex (normalized by R)  
EL(6)  $l_l$  (COMMON/SGAM) - Radial stations on  $l$  blade which shed elements of the vortex wake. Up to 6  $l_l$  can be used but normally only 3 are used, in which case they are defined as in LDS-73 with one exception. See definition of IABC in NAMELIST/WCOU (normalized by R)  
RHOK  $\rho_k$  (COMMON/SQCAL) - Nonburst value of  $\rho_c$  - vortex core radius (normalized by r)  
RHOG  $\rho_g$  (COMMON/SQCAL) - Burst value of  $\rho_c$  (normalized by R)  
AO  $a_o$  (COMMON/SQCAL) - Coning angle (zeroth harmonic of rigid body flapping) (radians)  
SM  $\sigma$  - Rotor solidity,  $\sigma = \frac{\text{rotor blade area}}{\text{rotor disk area}} = \frac{n_b C}{\pi R}$   
DPS1  $\Delta\psi$ (COMMON/SGAM) - Azimuth angle interval between positions of the  $\eta$  blade, which sheds points  $P_\eta$  at which distortion is computed (degrees)

- DM Determines the assignment of wake elements to either the near wake or the far wake. If the magnitude of the contribution to the induced velocity at point  $P_\eta$  of a group of wake elements is  $|\vec{q}_s|$ , then, when  $|\vec{q}_s|$  is greater than DM, those wake elements become part of the near wake relative to point  $P_\eta$  (normalized by tip speed) (Subsection 4.2.1)
- QMO (COMMON) - Minimum value of the induced velocity contribution of any vortex line or vortex sheet segment for which a special printout is made in QSVL, QCVL, or QVS (normalized by tip speed)
- QMB (COMMON) - If the induced velocity contribution of a bound vortex line is greater than QMB, integrate the induced velocity contribution over time (azimuth angle) as the blade sweeps through  $\Delta\psi$  in closed form instead of assuming that the induced velocity contribution remains constant during  $\Delta\psi$  (normalized by tip speed) (Subsection 4.1.8)
- FWD  $w_f$  (COMMON/SDCAL) - The increment in distortion ( $\bar{D}$ ) during an azimuth interval  $\Delta\psi$  is computed as FWD times the latest estimate plus (1.0-FWD) times the previous estimate (Subsection 4.2.4)
- RHOI  $\rho_I$  (COMMON/SWQC) - Vortex core radius of inboard trailing vortex line (normalized by R)
- RHOL  $\rho_L$  (COMMON/SWQC) - Vortex core radius of shed vortex lines (normalized by R)

#### H.2.2 NAMELIST/WCOU/

- NI Number of wake geometry iterations
- NC Number of cases - When a case is finished  $NC=NC-1$  and if NC is still greater than zero, WDAT and WCOU are read in and a new case is started
- IG (COMMON/SGAM) - Indicates type of circulation computation used.
- IG = 0: Compute bound circulation  $[\gamma_{bv}(\psi)]$  using angle-of-attack distribution  $[\alpha(\eta, \psi)]$  left over from a previous case.
- IG = 1: Compute  $\gamma_{bv}(\psi)$  using  $\alpha(\eta, \psi)$  read in from cards along with  $a = \partial C_L / \partial \alpha, \eta$ , and  $\Delta\eta$  in NAMELIST/ADETA

IG > 1: Set all  $\gamma_{bv}(\psi) = \gamma_o = \frac{2C_T/\sigma}{\pi(1 - \ell_2^2)}$  , no shed wake

IS (COMMON/SGAM) - Shed wake indicator

IS = 2: No shed wake

IS  $\neq$  2: Shed wake included

I1 (COMMON/SGAM) - Indicates initial wake model

I1 = 0: First iteration starting with rigid wake

I1 = n: nth iteration starting with  $\hat{D}$

read in from a previous run of WG-71

IABC (COMMON/SGAM) - Indicates wake model used

VS = vortex sheet, VL = one vortex line, nVL = n vortex lines

IABC	Tip Vortex	Inboard Trailing Wake	Shed Wake
0	VL	VS	VL
1	VL	none	VL
2	VL	VL	VL
3	VL	nVL	VL
4	VL	VL	VS
5	VL	VS	VS

When IABC = 0 or 5, an inboard trailing vortex sheet model is used. The outboard edge of this vortex sheet is located at radial station  $\ell_b$ . The value of  $\ell_b$  is constant for all azimuth angles and is equal to either  $\ell_2$  or the average location of the radial peak in bound circulation, whichever is smaller (Subsection 4.1.2).

IPS Controls punch out of distortion  $\hat{D}(\psi, \delta)$

IPS = 1: Punch only  $\hat{D}$  for last iteration

IPS = 2: No punch

IPS = 3: Punch  $\hat{D}$  for all iterations

IPR (COMMON/SDCAL) - Controls print out of intermediate  $\hat{D}$  results before each general update.

IPR = 0: No intermediate print

IPR = n: Intermediate print for azimuth angles:

$\psi = 0, n\Delta\psi, 2n\Delta\psi, \dots, 2\pi - n\Delta\psi$

IPLT Controls CALCOMP plots of wake geometry  
 IPLT = 0: No plots  
 IPLT = 1: Plot only last iteration  
 IPLT = 2: Plot all iterations

INPS Controls print out of  $\vec{D}$  at the end of each iteration except the last one. The  $\vec{D}$  for the last iteration is always printed in full. If INPS=n: print  $\vec{D}$  for azimuth angles:  
 $\psi = 0, n\Delta\psi, 2n\Delta\psi, \dots, 2\pi - n\Delta\psi$

NB  $n_b$  (COMMON/SGAM) - Number of rotor blades

NL  $n_\ell$  (COMMON/SGAM) - Number of radial stations  $\ell_\ell$  on the  $\ell$  blade. Use  $n_\ell = 3$ , except for IABC = 3 when  $n_\ell$  = number of trailing vortex lines.

ND (COMMON) - Value of subscript  $\ell$  for which wake distortion ( $\vec{D}$ ) is being computed. ND=NL for tip vortex

M m - Number of turns of wake whose distortion ( $\vec{D}$ ) is computed. This wake covers  $2\pi m$  in age.

MB M - Number of turns of wake below point  $P_\eta$  included in wake model for computing  $\vec{D}$  at point  $P_\eta$ . If the age of point  $P_\eta$  is  $\delta$  then the total azimuthal extent of the wake model is  $\delta + 2\pi M$  (Subsection 4.1.3).

LDM  $\ell_{DM}$  (COMMON/SDCAL) - General updating parameter. Every  $\ell_{DM}$  steps  $\Delta\psi$  in the boundary age  $\delta_M$  a general (distortion) update is executed (Subsection 4.2.3)

NDM(25)  $n_{DM}(\psi)$  (COMMON/SGAM) - Boundary updating parameter. At a given azimuth angle  $\psi$  a boundary (induced velocity) update is executed every  $n_{DM}(\psi)$  steps  $\Delta\psi$  in the age  $\delta$  (Subsection 4.2.2).

KPB(25) (COMMON/SQCAL) - Tip vortex core bursting occurs at azimuth  $\phi$  when point  $P_\ell$  reaches age  $\delta \geq \delta_b(\phi)$ .  $KPB(\phi) = 1 + \delta_b(\phi)/\Delta\psi$  [output by LDS-73]

### H.2.3 NAMELIST/ADETA/

A  $a = \frac{\partial C_L}{\partial \alpha}$  [ Same as LDS-73]

NE  $n_\eta$  - Number of radial stations in angle of attack distribution  
 $\alpha(\eta, \psi)$  input for circulation computation [same as LDS-73]  
 ETG(10)  $n_k$  - Radial stations of  $\alpha(\eta, \psi)$  [same as LDS-73]  
 DETA(10)  $\Delta n_k$  - Radial integration intervals for  $\alpha(\eta, \psi)$  [same as LDS-73]

### H.3 Sample Input Data for WG-71

#### & WDAT

EMU = .18  
 AMBDA = .0243 [same as LDS-73]  
 TANMU = .009  
 ETA = 1.0 [tip vortex]  
 EL = .10, .85, 1.0 EL(2) = .85 is the max. allowable  
 location of the outboard edge of  
 the inboard trailing vortex sheet  
 since IABC = 0 for this case  
  
 AO = .085  
 SM = .0622 [same as LDS-73]  
 DPS1 = 15.  
  
 DM = .0020 [use (.04 + .08)( $\lambda - \mu \tan i$ )]  
  
 RHOK = .0025 [same as LDS-73 with IVCN = 1]  
 RHOG = .10  
  
 RHOL = .105 [use  $\sim 0.4 \Delta \psi$ ]  
 RHOI = .30 [use  $\sim 0.5 (\ell_2 - \ell_1)$ ]  
 QMO = .015 [use (.5 + 1.0)( $\lambda - \mu \tan i$ )]  
 QMB = .0020 [about the same as DM]  
 FWD = .5

#### & WCOU

NI = 3 [sometimes 2 iterations is enough]  
 I1 = 0 [start with rigid wake]  
 NC = 1  
 IG = 1 [input  $\alpha(\eta, \psi)$ ]  
 IS = 1 [include shed wake - it makes a difference]  
 IABC = 0 [normally best choice]

IPS = 1 [punch  $\vec{D}$  for last iteration only]  
 IPR = 12 [intermediate print for  $\psi = 0^\circ, 180^\circ$ ]  
 IPLT = 2 [plot every iteration to check convergence]  
 INPS = 6 [print  $\vec{D}$  at  $\psi = 0^\circ, 90^\circ, 180^\circ, 270^\circ$  for all  
 but last iteration]  
 NB = 4 [4 bladed rotor]  
 NL = 3 [IABC = 0]  
 ND = 3 [tip vortex (ND = NL)]  
 M = 2 [m  $\sim 0.4/\mu$  is about right]  
 MB = 2  
 LDM = 12 general updating is expensive - not done very  
 frequently - every  $180^\circ$  works well normally  
 NDM = 6,6,6,7\*3,6\*6,7\*3,6,6,  
 boundary updating is less expensive - done every  
 $90^\circ$  fore and aft and every  $45^\circ$  along the sides  
 of rotor because there is more tip vortex inter-  
 action along the sides  
 KPB = 7\*49,4\*6,5,9,9,10,6\*49 [printed out by LDS-73]

#### & ADETA

A = 5.73  
 NE = 6  
 ETG = .25,.40,.55,.75,.85,.95, [same as LDS-73]  
 DETA = .225,.15,.225,.10,.10,.10  
 $\alpha$  cards from LDS-73 with  $\eta$  cards removed

#### & DPLT

ILAB = 1 [read in plot labels]  
 SR = 2 [scale factor in TPP  $\rightarrow$  radius = 2 inches]  
 SK = 2 [vertical scale factor]

The next two cards are the image of the two line label at the top of each CALCOMP plot. Anything in columns 1-60 of these two cards will appear on the plots.

The next cards are read by READ 10,J1,NS

10 FORMAT (I3,I2)

J1 is the subscript of the azimuthal position of the blade for which a CALCOMP plot is made. For example: J1=25  $\rightarrow \psi = 360^\circ$ , J1 = 13  $\rightarrow \psi = 180^\circ$ . NS controls the number of different starting  $\psi$ 's read in. When NS > 1, the program will try to read in another starting  $\psi$  card after it finishes the current plot.

There is a complete set of plot cards, starting with the scale factor card and ending with the starting  $\psi$  (blade position) cards, for each iteration whose  $\hat{D}$  is plotted.

#### H.4 WG-71 Outputs

##### H.4.1 Printed Output

The printed output is presented in the order in which it is output.

- 1) Label plus input data from WDAT and WCOU - output by MAIN
- 2) Bound circulation  $\gamma_{bv}(\psi)$  and  $\ell_2$  - output by WGAM
- 3) Iteration number - output by MAIN
- 4) Special print for any vortex line or vortex sheet segment whose contribution to the induced velocity at point  $P_\eta$  is greater than QMO - output by QSVL, QCVL, and QVS
- 5) Intermediate distortion results, output before each general update.

At this point in the computation  $KDLL = 1 + \delta_M / \Delta\psi$ . The index N refers to the vector components: N = 1 -  $\hat{i}$ , N = 2 -  $\hat{j}$ , N = 3 -  $\hat{k}$ .

The index J gives the azimuth angle: J = 1 +  $\psi \Delta\psi$ . These results are only output for selected  $\psi$  controlled by the input IPR. The unlabeled numbers are  $\hat{D}(\psi, \delta)$  starting at  $\delta = \Delta\psi$  and going to  $\delta = 2\pi m$ .

The labeled numbers are: DS =  $\hat{D}_s(\psi)$ , DSN =  $\hat{D}_N(\psi)$ , DVO =  $\hat{D}_o(\psi)$ , CUR =  $\hat{q}_D(\psi)$ , VEL =  $\hat{q}_F(\psi, \delta_M)$ , and QBV =  $\hat{q}_{BV}$  - output by DCAIC.

- 6) Transition points  $KTR = \delta_T(\zeta, \psi, k) / \Delta\psi$ . Under each  $PSI = \psi$  the KTR for the different values of  $\zeta$  are listed in rows: 1st row -  $\zeta = 0$ , 2nd row -  $\zeta = \Delta\zeta$ , etc. Within a row, the numbers are in order by  $k$ , from  $k = 1$  to  $k_m(\zeta, \psi)$  - output by MAIN.
- 7) Main output of  $\vec{D}(\psi, \delta)$  and  $\vec{q}_F(\psi, \delta)$ . Each page is for a given value of azimuth angle  $PSI = \psi$  or starting azimuth angle  $PSI - S = \psi_s = \psi + \delta$ . Column 1 is the age  $DELTA = \delta$ . The next 6 columns are for the given  $\psi$ . Columns 2-4 are the  $\vec{i}$ ,  $\vec{j}$ , and  $\vec{k}$  components of  $\vec{D}(PSI) = \vec{D}(\psi, \delta)$ . Columns 5-7 are the  $\vec{i}$ ,  $\vec{j}$ , and  $\vec{k}$  components of  $VEL(PSI) = \vec{q}_F(\psi, \delta)$ . The remaining 7 columns are for the given  $\psi_s = \psi + \delta$ . These columns are useful for plotting the distortion of a given tip vortex line, because they are all for the same  $\psi_s$ . The starting azimuth angle  $\psi_s$  is the position of the  $\eta$  blade at age  $\delta$ . Hence it is where the tip vortex line starts. Column 8 is  $\psi = \psi_s - \delta$ , where  $\delta$  comes from column 1 and  $\psi_s$  from the top of the page. Columns 9-11 are the  $\vec{i}$ ,  $\vec{j}$ , and  $\vec{k}$  components of  $\vec{D}(\psi, \delta)$ , where  $\psi$  comes from column 8. Column 12 (DK) is column 11 plus  $\delta \mu_{tani}$ . This is the actual vertical displacement of point  $P_\eta$  since age zero. Column 13 (VK) is the average downwash required to give column 12 (DK),  $VK = DK/\delta$ . Column 14 (WK) is the average downwash required to give column 4  $WK = D_k(\psi, \delta)/\delta$  - output by MAIN.
- 8) Execution times in hundredths of a second - output by MAIN.
- 9) Repeat numbers 3 through 8 for each iteration.

#### H.4.2 Punched Output

The only punched output is the distortion  $\vec{D}(\psi, \delta)$ . This data can be used as input to LDS-73 for a distorted wake run or to WG-71 for more distortion iterations. Normally,  $\vec{D}(\psi, \delta)$  is only punched out for the last iteration; however, this can be controlled by input IPS.

```

DO 10 K=1, NPHI
10    PUNCH 20, ((D(I,J,K), I=1,3), J=1, NPSI)
20    FORMAT (6E13.6)
```

#### H.4.3 CALCOMP Plots

Subroutine SPLOT makes Calcomp plots of  $D(\psi, \delta)$ . The input IPLT controls the calling of SPLOT. Subroutine SPLOT reads in two lines of labels, up to 60 characters long, which are printed at the top of each plot. It also reads values for the starting azimuth angle  $\psi_s$ . There is a separate plot for each  $\psi_s$ . Each plot consists of a top view (perpendicular to the TPP) and a side view of the tip vortex of the  $\eta$  blade from  $\delta = 0$  to  $\delta = 2\pi m$ . Both the rigid wake and the distorted wake versions of the tip vortex are shown. For an example, see Fig. 1.

#### H.5 Selected Variables Used by WG-71

To aid the reading of the listing of WG-71 in Appendix I, the most important variables are defined here. When possible, a variable is defined by reference to symbols defined in the List of Symbols or by reference to the input namelists WDAT, WCOU, and ADETA (Subsection H.2).

A	$a = \frac{\partial C_L}{\partial \alpha}$ (input ADETA)
ALPHA(10,25)	$\alpha(\eta, \psi)$ - input from LDS-73
AMBDA	$\lambda$ (input WDAT)
ANG(25)	$\psi$ (degrees)
AO	$a_o$ (input WDAT)
AXBI, AXBJ, AXBK	$(axb)_i, (axb)_j, (axb)_k$
AXBS	$ \vec{axb} $
BOER	$b/2R$
BVG(6,25)	$\frac{b}{2R} \gamma_{bv}(\ell, \phi)$
CUR(3,25)	$\vec{q}_o(\psi)$
D(3,25,97)	$\vec{D}(\psi, \delta)$
DANG	$\Delta\psi$ (radians)
DELL	$\Delta x$
DELTA	$\delta$
DETA(10)	$\Delta\eta_k$ (input ADETA)
DM	(input WDAT)
DPSI	$\Delta\psi$ (degrees) (input WDAT)

DS (3,25)	$\vec{D}_S(\psi)$
DSMI,DSMJ,DSMK	i, j, and k components of $\Delta q$
DSN (3,25)	$\vec{D}_N(\psi)$
DVO (3,25)	$\vec{D}_O(\psi)$
D3 (3)	$\vec{D}_\eta(\psi, \delta)$
EL (6)	$\ell_\ell$ (input WDAT)
EMU	$\mu$ (input WDAT)
ETA	$\eta$ (input WDAT)
ETACP	$\eta \cos \psi$
ETASP	$\eta \sin \psi$
ETG (10)	$\eta_k$ (input ADETA)
FWD	$w_f$ (input WDAT)
GA, GB	$\gamma_a, \gamma_b$
GBV (6,25)	$\frac{b}{2R} \gamma_t(\ell, \phi)$
GS (6.25)	$\frac{b}{2R} \gamma_s(\ell, \phi)$
GZER	$\gamma_o = \frac{2(c_T/\sigma)}{\pi(1 - \ell_2^2)}$
I	$1 + \zeta/\Delta\zeta$
IABC	(input WCOU)
IG	(input WCOU)
INPS	(input WCOU)
IPLT	(input WCOU)
IPR	(input WCOU)
IPS	(input WCOU)
IS	(input WCOU)
I1	(input WCOU)
J	$1 + \psi/\Delta\psi$
K	k in $\delta_T(\psi, \zeta, k)$
KDLL	$\delta_M/\Delta\psi$ normally, however KDLL = $1 + \delta_M/\Delta\psi$ just before a general update
KDLS	$1 + \delta_M/\Delta\psi$

KM(6,25)	$k_m(\zeta, \psi)$
KP	$1 + \delta_\ell / \Delta\psi$
KPB(25)	$1 + \delta_b(\phi) / \Delta\psi$ (input WCOU)
KPHI	$1 + \phi / \Delta\psi$ , principal value only $1 \leq KPHI \leq NPSI$
KSTRT	$1 + \delta_{ST} / \Delta\psi$
KT	Value of KTR for end of current near wake section of wake
KTR(6,25,16)	$\delta_T(\zeta, \psi, k) / \Delta\psi$
L	Index $\ell$ from $\ell_\ell$
LD	$1 + \delta_D / \Delta\psi$
LDM	$\ell_{DM}$ (input WCOU)
LG	$L - 1$
LL	$1 + \delta / \Delta\psi$
LL1	$1 + \delta_1 / \Delta\psi$
LS	$1 + \delta_s / \Delta\psi$
M	$m$ (input WCOU)
MB	$M$ (input WCOU)
MGO	Indicates current state of distortion iteration, See Subsection 4.2.5.
NB	$n_b$ (input WCOU)
NBIGM	$2\pi M / \Delta\psi$
NC	(input WCOU)
ND	(input WCOU)
NDI	$\Delta\zeta / \Delta\psi$
NDM(25)	$n_{DM}(\psi)$ (input WCOU)
NE	$n_\eta$ (input ADETA)
NGO	Indicates curved tip vortex-line segment when $NGO = 2$
NI	(input WCOU)
NL	$n_\ell$ (input WCOU)

NPHI	$1 + 2\pi m / \Delta\psi$ - number of age stations $\delta$
NPSI	$n_\psi = 1 + 2\pi / \Delta\psi$
OKPHI	$1 + (\phi - \Delta\psi) / \Delta\psi$ , principal value only $1 \leq \text{OKPHI} \leq \text{NPSI}$
OLD(3)	$\vec{\Delta D}_O$
OLDM	When $\text{OLDM} = 0$ , there is a boundary update; i.e., $(\delta - \Delta\psi) / \Delta\psi$ is an integral multiple of $n_{DM}(\psi)$
OVI(6), OVJ(6), OVK(6)	Vectors $\vec{a}$ or $\vec{b}$ from point $P_\eta$ to various points $P_\ell$ as a function of $\ell_\ell$ for the previous age $\delta_\ell + \Delta\psi$
PHI	$\phi$ (radians)
PSI(25)	$\psi$ (radians)
PZAP	$\psi + \zeta - \phi = \delta_\ell - \delta = \delta_R$
QBV(3)	$\vec{q}_{BV}$
QMB	(input WDAT)
QMO	(input WDAT)
PHOC	$\rho_c$
RHOG	$\rho_g$ (input WDAT)
RHOI	$\rho_I$ (input WDAT)
RHOK	$\rho_k$ (input WDAT)
RHOL	$\rho_L$ (input WDAT)
SKPHI	$1 + (\phi - 2\Delta\psi) / \Delta\psi$ , principal value only $1 \leq \text{SKPHI} \leq \text{NPSI}$
SM	$\sigma$ (input WDAT)
START	$2\pi m$
SUMI, SUMJ, SUMK	$\vec{i}, \vec{j}$ , and $\vec{k}$ components of $\Sigma \vec{q}$
SVI(6), SVJ(6), SVK(6)	Same as OVI(6), etc., but for age $\delta_\ell + 2\Delta\psi$ , used for curved-tip vortex-line segments.
TAMB	$\lambda - \mu \tan i$
TANMU	$\mu \tan i$ (input WDAT)
TOT(3,25)	$\vec{q}_{TOT}(\psi)$
VEL(3,25,97)	$\vec{q}_F(\psi, \delta)$
VI(6), VJ(6), VK(6)	Vectors $\vec{a}$ or $\vec{b}$ from point $P_\eta$ to various points $P_\ell$ as a function of $\ell_\ell$ for the current $\delta_\ell$
XA, YA, ZA	$x_a, y_a, z_a$

**XB,YB,ZB**

$x_b, y_b, z_b$

**ZETA**

$\zeta$

**ZM**

$z_m$

## APPENDIX I

### LISTING OF WG-71

This program is normally compiled and executed on an IBM 370/168 running under release 21.7 of OS/MVT (Operating System/Multiprogramming with a Variable number of Tasks) with release 21.6 of FORTRAN G1. The core storage requirement is 200k. Subroutine SPLOT make plots of the tip vortex geometry on a CALCOMP 563 Drum Plotter with a CALCOMP 905 Controller. If no plots are required remove statements MAIN0039, MAIN0040, MAIN0162, MAIN0163, MAIN0164, MAIN0165, MAIN0166, MAIN0189, and Subroutines SETCAL and SPLOT.

## BIOGRAPHY

Michael P. Scully was born on November 17, 1942 in Albany, California. After graduation from Pleasant Hill High School in Pleasant Hill, California he entered M.I.T. in 1960. He received a Bachelor of Science Degree from the Department of Aeronautics and Astronautics in June 1964. A four-month CO-OP work period was spent at Boeing, Seattle in 1962/3. Entering graduate school at the Massachusetts Institute of Technology, Department of Aeronautics and Astronautics in September 1964, he received a Master of Science Degree and an Engineer in Aeronautics and Astronautics Degree in June 1967. He entered the doctoral program at the M.I.T. Department of Aeronautics and Astronautics in September 1967. His graduate education has been supported by a full-time Research Assistantship with both the Aeroelastic and Structures Research Laboratory and the Flight Transportation Laboratory. In addition, there were two summer DSR staff appointments and a short period on National Science Foundation Traineeship.
